The smegma bacilli differ from the tubercle bacilli in being more slender and not granular, and not exhibiting the characteristic groupings of the tubercle bacilli. (See Figs. 269 and 280.) Finally, when the stained preparations are afterward treated with HCl alcohol for from five to ten minutes, the smegma bacilli become decolorized, but not the tubercle bacilli. Grette recommended combining the counterstaining effect of methylene-blue with the decolorized action of the alcohol.¹ He stains as ordinarily with carbol-fuchsin, and after washing with water he treats the specimen with a concentrated alcoholic solution of methylene-blue (without acid). With this method the tubercle bacilli remain red, whereas all the rest of the preparation, including the smegma bacilli, is stained blue. Another difference between them is that Gram's stain decolorizes the smegma but not the tubercle bacillus. Finally, the tubercle but not the smegma bacilli are changed to formations like strings of pearls, resembling streptococci, by excessively heating the dry preparation, i. e., by passing it perhaps ten times through the flame. Compare also the staining method recommended by Pappenheim for distinguishing tubercle bacilli from smegma bacilli in the sputum. The employment of Ebner's decolorizing fluid will also prevent the confusion of these bacilli. (See p. 712.)

The presence of gonococci in the urine sediment is also of diagnostic interest. (See Fig. 270.)

Fig. 272.—Embryos of *Filaria sanguinis*: Length, 0.0075 to 0.21 mm.; thickness, 0.004 to 0.36 mm. (after Scheube).

Fig. 273.—Eggs of *Distomum hæmatobium* (*Bilharzia hæmatobia*): Length, 0.12 mm.; breadth, 0.05 mm. (after Bilharz).

The *bladder catarrh* and *pyelitis* which may complicate gonorrhea never depend upon a pure gonorrheal infection, but upon secondary infections of the urinary tract with other organisms. At the same time, in such cases, if the disease has not been entirely cured, pus-corpuscles which contain gonococci are sometimes found in the sediment. They have probably become mixed with the urine from the urethra. Fig. 270 shows the characteristic arrangement of the gonococci in the interior of the pus-cells. A diagnosis of gonorrhea is permissible only when this characteristic intercellular arrangement has been recognized, because the same biscuit-like grouping so characteristic of diplococci is also seen with the ordinary staphylococci. Another characteristic of gonococci is that they do not grow upon ordinary culture-media.

Braatz² found actinomycosis granules in a case of actinomycosis of the urinary tract (Figs. 292 and 293).

In diabetic urine a rapid yeast growth is sometimes produced by the presence of yeast fungi. The sugar becomes fermented, carbon dioxide bubbles are formed, and yeast spores settle in the sediment. Hence, the demonstration of yeast fungi in the urine may suggest the diagnosis of diabetes; but even non-saccharine urine may exhibit yeast-like fungi.

² Petersburg. med. Woch., 1888, No. 13.

ANIMAL PARASITES

Echinococcus of the urinary tract and of the kidneys may cause fragments of **echinococcus** cysts and hooklets or whole daughter cysts to be voided in the urine (Fig. 271).

Embryos of *Filaria sanguinis* (Fig. 272) are found in the urine in the tropic hematochyluria, and the eggs of *Distomum hæmatobium* (*Bilharzia hæmatobia*, Fig. 273) in the Egyptian hematuria.¹ It remains to be mentioned, finally, that in rare cases the trichomonas is found in the urine in disease of the urinary tract. This species is probably identical with that occurring in the intestine (*Trichomonas intestinalis*; compare p. 518 and Fig. 216).

EXAMINATION OF THE SPUTUM

Expectoration, or sputum, is what is discharged by coughing or clearing the throat. It is composed of the secretion or exudate from the respiratory mucous membrane of the nose, pharynx, and trachea down to the finest bronchi and alveoli; of material which has reached the respiratory tract from neighboring regions (pus of abscesses and empyema); of blood derived from somewhere along the respiratory tract; and, finally, of material from the buccal cavity or from any part of the digestive tract. Macroscopic and microscopic foreign bodies which have entered the respiratory system from without are usually discharged in the expectoration.

On account of its numerous sources of origin, the composition of the sputum is very complex and of great symptomatologic importance. The sputum is not always expectorated. Small children swallow their sputum; and occasionally adults do the same, as the result of bad habits, lack of practice in expectorating, or of impaired consciousness. Its help in diagnosis is then lost. Some of these adults and most older children can be taught to expectorate, or a reflex expectoration may be incited by touching the base of the tongue, epiglottis, or uvula with a tongue depressor. Sputum may be obtained from children by introducing a finger wrapped with gauze well into the throat. The resulting cough reflex will bring up sputum, which will stick to the gauze. For diagnostic purposes, the expectoration for twenty-four hours is collected most conveniently in a transparent sputum cup.

AMOUNT OF SPUTUM

The amount of sputum may vary greatly, depending upon what process produces it. Some pulmonary patients, in spite of violent coughing, expectorate only a small quantity, and that usually very tenacious (dry bronchitis, incipient phthisis). Others may expectorate large quantities during the day, or even at one time (in certain types of chronic bronchitis sometimes called bronchorrhea, in advanced pulmonary tuberculosis, in bronchiectasis, in pulmonary edema, in pulmonary hemorrhages, and in perforation of abscesses or an empyema into the air-passages). The special characters of these various types of sputum will be discussed later on.

¹ Rüttimeyer, Mittheilungen aus kliniken und medicinischen Instituten der Schweiz, 1894, vol. i.

CONSISTENCE OF THE SPUTUM

The consistence of the sputum bears a certain relation to its amount. If very abundant, a sputum is usually less tenacious than if scanty. Ordinary sputum is mucoid; it may, however, be either serous, purulent, or bloody. The peculiar mucoid (slimy) consistence of sputum depends largely upon the amount of mucus it contains, since the mucin-like substances excreted from the respiratory mucous membrane form a considerable portion of the expectoration.¹ The stickiness of the sputum also is partly due to mucus and partly, in some cases, to its protein content, especially the sputum of croupous pneumonia, the viscosity and tenacity of which are largely due to the amount of nuclein contained.

REACTION OF THE SPUTUM

The reaction of fresh sputum is generally alkaline. It may become acid, after standing for some time, from bacterial decomposition.

COLOR AND TRANSPARENCY OF THE SPUTUM

The color of the sputum varies decidedly. Pure *mucoid* or *glassy sputum* may be perfectly colorless, but its consistence prevents its being easily mistaken for saliva. Admixture of white blood-corpuscles makes this slimy secretion more and more yellow or greenish, and also cloudy and opaque. It is not clear why the color in one case is more yellow, and in another more greenish, any more than in the case of pus. But as the more intense inflammations are usually associated with the transudation of red blood-corpuscles, it seems fair to assume that the green derivatives of blood-pigment usually produce the greenish pus color. (See later with reference to other causes of green discoloration of the sputum.)

A *mucopurulent sputum* consists of an admixture of masses of pure mucus with masses of pus, or of a moderate but uniform admixture of the two elements, the whole appearing but slightly clouded. *Purulent sputum* is the next step in such admixtures. Its consistence is still mucoid, unless composed of pure pus (either thick or thin) derived from an abscess or from the perforation of an empyema, and expectorated as such without any mucus.

Serous sputum is another type of colorless expectoration. It differs from the pure mucoid or glassy sputum in its very liquid consistence and foamy appearance. It occurs in pulmonary edema, and in the very rare perforation of serous pleural exudates into the lung. Serous sputum is frequently slightly tinged with blood.

Sputum has a slightly reddish color whenever mixed with blood. In some cases the sputum consists of pure blood; in other cases it contains only a slight admixture, producing a salmon color. Between these two extremes all sorts of transitional forms occur. Hemorrhagic sputum is observed in traumatic and tuberculous hemorrhages from the lungs, in hemorrhagic infarctions of the lungs, in pneumonia (especially in croupous pneumonia), in gangrene of the lung, in tumors of the

¹ The mucus of the respiratory apparatus appears to be composed mostly of true mucin (Cohnheim, *Chemie der Eiweisskörper*, Braunschweig, Vieweg, 1900; F. Müller, *Beiträge zur Kenntnis des Mucins*, etc., *Zeit. f. Biol.*, vol. xlii).

Lung, and finally in congestion of the pulmonary circulation. The different shades of blood containing sputa will be described below.

Certain derivatives of blood-pigment produce in the sputum very similar shades to that of bloody sputum proper. Rusty sputum, the most common type in pneumonia, is an instance. The coloring-matter is here partly unchanged blood, partly, however, certain derivatives of the blood-pigment, about which little is as yet known. Among these may be mentioned methemoglobin or bilirubin (hematoidin). Peculiar lemon-colored and dirty green to grass-green shades, the effect of further chemical transformation of the blood-pigment, are infrequently observed in pneumonia sputum. All these variations are analogous to the changes of blood-pigment observed in subcutaneous ecchymoses. Such sputa respond to Gmelin's test for bile-pigment (see p. 575 et seq.), and also contain bilirubin. Lemon-yellow and greenish sputa in pneumonia are frequently called icteric sputum. This name is, however, justifiable only when there is general jaundice or, at least, some icteric discoloration of the conjunctivæ, or when bile-pigment is contained in the urine. A peculiar light-brown shade characterizes sputum which contains abundant cells of heart disease. (See Plate 8, Fig. 3.) Here amorphous blood-pigment is found encapsulated in the pulmonary epithelium. The brownish or ochre-like color of the sputum which is occasionally observed in destructive processes of the lung, especially in pulmonary abscesses, or in a liver abscess which has perforated into the lung, is due to hematoidin crystals, apparently identical with bilirubin. (See Fig. 278, *d*, p. 707.) In the expectoration from a liver abscess the hematoidin or bilirubin crystals are derived not from the blood, but from the admixture of bile with the pus. The bitter taste noticed by patients when expectorating such sputum depends upon the presence of biliary salts. Gmelin's reaction for bile-pigment will not differentiate the source of the hematoidin or bilirubin, as they react in the same way, whether derived from blood or from bile.

True icteric sputa, such as has been observed in certain cases of pneumonia, which are complicated by jaundice, or with any other pulmonary affections with jaundice (see p. 42 et seq.), may present various shades of color, due to the oxidizing of bilirubin. Yellow and then dirty-green shades are the most common.

A rather different type of green sputum has been described in lung tumors, but the nature of the pigment in question is as yet unknown. The sputum in certain pulmonary tumors (chloroma; see Examination of the Blood, Leukemia) which belong to the lymphadenomata is greenish in color. Hence a greenish sputum in a supposed tumor of the lung would suggest a chloroma; but green sputum has been observed in cases of carcinoma. It is, however, usually easy to diagnose chloroma from other symptoms, especially the involvement of the bones of the skull and the frequently associated blood-picture of leukemia. The pigment of chloroma dissolves in alcohol. Too much attention has probably been devoted to the green sputum in tumors of the lung, because, as we shall see, the multiplication of chromogenic bacteria may cause a greenish coloration of sputum outside of the body in almost any affection.

Other striking colorations of sputum have been observed from the admixture of inhaled dust-particles. Black sputum belongs to this class. Its pigment is due to inhaled coal-dust or soot, of which, as is well known, normal lung pigment consists. A small portion of the

carbon is free in the sputum; the larger part is contained in the interior of round or oval epithelium and white blood-cells. (See p. 704.) Particles of soot look like amorphous granules, but under the microscope we can frequently recognize the vegetable structure of the larger particles of carbon. These are usually not contained in the cells, but are found free. The gray or blackish discoloration of such sputa, as well as the degree of lung pigmentation, depends chiefly upon the individual's occupation. The sputa of coal-miners and workers in coal are frequently intensely black (anthracosis of the lung). Other *pneumonokonioses* (i. e., changes in the lung produced by the inhalation of dust) are associated with peculiar coloration of the sputum. Workmen (e. g., in polishing mirrors) who breathe the dust of oxid of iron (English-red, caput mortuum), and who have thereby acquired siderosis of the lung, may expectorate an ochre-colored sputum. The reddish particles are, for the most part, inclosed within the cells. To demonstrate siderosis from the sputum, add hydrochloric acid and a solution of ferrocyanid of potash; Berlin blue will then be formed. Blue sputum has been observed in men working in ultramarine.

These colorations of the sputum are not due to the pigment which has impregnated the lung, for whatever pigment particles are deposited in the lung probably never leave it; they should rather be considered as coeffects of the same cause, viz., inhalation of dust. Only the dust which has been recently inhaled, and which has not penetrated the interior of the pulmonary tissue, is expectorated. Consequently the characteristic coloration of the sputum will disappear soon after the patient gives up the occupation that produced it, although the *pneumonokoniosis* will persist. Colored sputum should be considered rather as a sign of the inhalation of dust than of *pneumonokoniosis*. Where the characteristic discoloration of the sputum continues or reappears after the individual has been removed for some length of time from the specific dusty atmosphere, it generally means that some destructive process, usually tuberculosis, is added to the *pneumonokoniosis*.

The "gluing" or "smearing" of the respiratory passages, described by Gerhardt and Lublinski,¹ which occurs in bakers and millers should be mentioned. Here paste-like masses are expectorated. It is due to the inhalation of flour.

The manifold colorations of the sputum due to admixtures from without, and not from the air-passages, should be mentioned, e. g., when patients take milk, eggs, claret, coffee, chocolate, licorice, or some colored medicine before expectorating, the sputum is apt to become discolored in the mouth. A green discoloration of the sputum is sometimes due to the growth of certain chromogenic bacteria, especially the *Bacillus virescens*.² Yellow, bluish, and reddish sputa of probable bacteriologic origin have also been observed. The parasite of "blue pus" (*Bacillus pyocyaneus*) probably thrives in sputum under certain conditions.³

AIR CONTENT OF THE SPUTUM

Sputum is often more or less distinctly foamy or frothy, due to the presence of air. Other things being equal, the amount of air contained in sputum is greater the finer the bronchi from which it is derived. This is because air is most easily incorporated with tiny masses of spu-

¹ Gerhardt, Centralbl. f. inn. Med., 1896, No. 20; Lublinski, *ibid.*, 1896, No. 28.

² See Frick, Virchow's Arch., 1889, vol. cxvi, p. 226.

³ [Norris isolated from the sputum of a case of chronic bronchitis a bacillus which could not be differentiated from the *Bacillus pyocyaneus*. This sputum when first expectorated was colorless, but developed an intense greenish color upon standing less than three hours. The literature contains a number of similar instances.—Ed.]

tum, as they are being collected into large masses, while passing from the smaller to the larger bronchi. The consistence of the sputum is also of importance. Thin sputum is usually very frothy. Thick, tough sputum is less so. The amount of air contained in the sputum can be readily recognized by its specific gravity. Air-containing sputum will float on the water in a sputum-cup; airless sputum will sink. The sinking of sputum (*sputa fundum petentia*) has been considered a proof of its derivation from a cavity of the lungs. Evidently, sputum derived from the pus of pulmonary cavities will ordinarily contain but a slight amount of air; but so may purely catarrhal secretion from the larger bronchi, so that this test is of slight diagnostic value, and then only in connection with other signs.

SPUTUM STRATA

Sputa which settle in layers in the cup are observed chiefly in bronchorrhea (chronic bronchitis with abundant secretion), in bronchiectasis, in putrid bronchitis, and in gangrene of the lung. The sputum is profuse and very fluid in all these conditions, and, besides, is rich in morphologic elements, pus in the one, shreds of parenchyma in the last named, gangrene. There are usually three layers—an uppermost, aerated and floating portion; a middle, fluid layer, consisting chiefly of purulent serum or mucoid fluid; and a third layer, the sediment, which consists of pus-corpuscles, gangrenous shreds of lung tissue, and molecular lung detritus.

ODOR OF THE SPUTUM

Fresh sputum rarely has any particular odor; but upon standing a short time it may acquire a disagreeable odor, due to the action of bacteria. Freshly expectorated sputum has a very strong offensive odor in purulent bronchitis, in many cases of pulmonary tuberculosis, and bronchiectasis and pulmonary gangrene, and very frequently in pulmonary abscess and in empyema which perforates the lung. The disagreeable odor in these cases arises from the growth of putrefactive bacteria even before the expectoration of the sputum. Stagnation of the secretion in cavities favors the processes of decomposition. The foul odor of the contents of the lung is usually imparted to the exhaled breath, where it may even be more distinct than in the sputum itself. This is frequently noticed in consumptives. The peculiar carrion-like odor of the breath so characteristic of this disease will sometimes point to pulmonary tuberculosis even before definite pathologic signs are plainly evident in the chest, and while the sputum may be remarkably free from odor. We should then naturally suspect that the foul odor came from the mouth, although the futility of cleansing the mouth with such deodorants as permanganate of potash or dioxid of hydrogen proves that the offensive odor originates in the depths of the lung. This is very likely due to the fact that the warm air in the lung takes up odors more readily than the external air at room temperature. Besides, sputum may very rapidly lose its odor upon standing from evaporation of its upper layers. The same is true of the fecal vomitus in intestinal obstruction. It seems to the author probable, and his idea is confirmed by others, that consumptives with this char-

acteristic odor usually have cavities (even if quite small) in which the secretion stagnates.

The sputum may have a peculiar odor after the administration of myrrh, oil of turpentine, ether, alcohol, paraldehyd, etc. It has been assumed that these substances are partly eliminated by the lungs.

CHARACTERISTIC GROSS APPEARANCES OF THE SPUTUM AND ITS ADMIXTURES

Many sputa appear to the eye perfectly homogeneous—pure mucous, pure purulent, pure bloody, etc. But sometimes not only may the sputa from one patient vary, but differences can be distinguished in each individual expectorated mass. Particularly in mucopurulent sputum the particles of mucus and pus may alternate. From the quantity of these individual constituents we can judge more or less correctly whether the sputum arises from a larger or a smaller bronchus.

Fig. 274.—Curschmann's spirals: I, Natural size; II and III, enlarged: a, a, a central fiber (after Curschmann).

A peculiar fine, flocculent, shaggy appearance of purulent sputum is very characteristic of the slow emptying of a pleural empyema or of a pulmonary abscess. The flocculi can be best seen if the sputum be suspended in water. They are probably due to the fact that the pus is pressed into the shape of shreds or strands in being squeezed through the narrow seat of perforation. These shreds become surrounded by mucus, and are then no longer confluent.

To detect other admixtures which exhibit a microscopic difference from the main bulk of the sputum, it is advisable to examine a small portion of the sputum upon a plate one-half of which has been painted with black enamel paint, so that the background may be either black or white, as desired. In this way it is easy to select ropy, fibrous, generally dirty, dark particles or larger grayish-black shreds characteristic of necrotic lung tissue. If elastic fibers (Fig. 277) be detected by the microscope, the diagnosis is confirmed. These, however, may be absent

in gangrene of the lungs (p. 706). Bits of necrotic cartilage in ulcerative processes of the bronchi, trachea, or larynx, and tumor fragments in tumors of the lungs or bronchi, may be detected in the same way.

"Dittrich's plugs," yellowish-white bits the size of a mustard seed, are very conspicuous when looked for over a dark background. They come from the smaller bronchi in putrid diseases of the lungs, especially in putrid bronchiectasis and in pulmonary gangrene. Microscopically, they consist of clumps of bacteria and crystals of fatty acids (compare Fig. 278, *a*). They have a very intense and disagreeable odor.

Similar plugs may be seen mixed in the sputum in follicular tonsillitis from the crypts of the tonsils.

"Dittrich's plugs" should not be confused with the spiral formations described by and named after Curschmann. These are represented in Fig. 274: I, natural size; II and III, slightly magnified. They consist of long or short, worm-like formations, 1 and 2 cm. long and about 1 mm. thick, more or less opaque, and usually suspended in a glassy menstruum. They are shiny, viscid in consistence, are visible to the naked eye, and are composed of shreds twisted into a spiral. They are only rarely branched. Some of them exhibit a central, more strongly refractive fiber in the axis of the spiral (Fig. 274, II, *a* and III, *a*). Other formations which resemble these central fibers occur in sputum, but they are isolated and not surrounded by spirals. A. Schmidt¹ showed, by staining, that Curschmann's spirals and the central fibers consist of a mucin-like substance and not of fibrin, as was formerly supposed. They are not so dense as the shreds of fibrin which occur in the sputum. These spirals of Curschmann are portions of the secretion or exudate which forms in the finest bronchi as the product of a so-called *bronchiolitis exudativa*. Curschmann's spirals are more or less characteristic of asthma sputum. After the end of a typical attack they are sometimes found in extraordinary numbers. We must not, however, suppose that Curschmann's spirals are pathognomonic of asthma, for not only do cases of asthma occur without spirals, but spirals may be found in the sputum of a bronchitis without asthma. They are sometimes found in croupous pneumonia, in which case there is a very good opportunity to distinguish them from bits of fibrin. When strongly magnified, the spirals will frequently be found to contain white blood-corpuscles and Charcot's crystals (Fig. 278, *e*). These leukocytes, particularly in cases of bronchial asthma, are conspicuously, for the most part, mononuclear, and contain eosinophilic granules.

Curschmann's spirals can be preserved in glycerin. Their mode of origin is by no means definitely known. Doubtless their shape is due to the screw-like movement of the mucus while passing through the bronchi. Personally, the author prefers to consider that this spiral motion is caused by the movement of the cilia of the bronchial epithelium, although we do not yet know whether the direction of the motion of the cilia in the bronchial mucous membrane of man is spiral or not. But even if the cilia should be proved to vibrate in the axis of the bronchi, the progress of the sputum from the lateral branches would exert a tangential force and so cause a twisting motion to the ball of sputum. Senator assumes that the screw-like shape of these structures is brought about by physical means, and that it is analogous to the spiral-like mass of a salve which is forced out of a compressible tube by pressure—the reason for which is that the resistance over the entire circumference is never exactly equal and so its contents necessarily move laterally, and secondarily a twisting motion results.

¹ Zeit. f. klin. Med., 1892, vol. xx, p. 476.

Formations consisting of fibrin may be found in the sputum under various conditions. They are easily recognized by their white color, by their tenacious consistence, and sometimes by their shape. In diphtheria of the pharynx, larynx, and trachea, the expectorated fibrinous pseudomembranes consist of shapeless masses or casts of these organs. Diphtheria not infrequently reaches as far as the bronchi, and branching, tree-like bronchial casts may be expectorated. They are readily recognized and are important in diagnosing the extension of the disease to the lungs, and so determining the prognosis. Similar branching bronchial casts are observed still more frequently in croupous pneumonia, because the bronchial mucous membrane usually participates in the fibrinous inflammatory process. Fig. 275 represents a cast of this sort. Large numbers of such casts are often contained in the sputum of pneumonia. They look like white strands or shreds. To investigate their nature more accurately, they should be isolated by shaking the portion of sputum which contains them in a test-tube with water. All other

formations lose their shape, whereas these casts float about in the water. These tree-like formations may be solid or hollow. Similar formations are found in the sputum of patients with fibrinous or croupous bronchitis. The etiology of this disease has not been investigated carefully. Its course is usually chronic, very rarely acute. The sputum is more or less blood-tinged, and not infrequently contains beautiful branching casts of very large bronchi. Hochhaus has proved that some of these casts (coagula) in the disease under discussion are composed of mucin. Under the microscope these fibrinous casts show the ordinary coarse structure of fibrin and the same power of refracting light. Like

Fig. 275.—Fibrinous bronchial casts.

Curschmann's spirals, they often contain Charcot's crystals (Fig. 278, c). Fibrin coagula can be distinguished both macroscopically and microscopically from mucous constituents of the sputum by their swelling and becoming more translucent after the addition of acetic acid. If fresh fibrin be submerged in dioxid of hydrogen, gas will develop much more quickly than in the case of mucus (catalytic action of the peroxydases of fibrin).

Foreign bodies are sometimes aspirated. They may even remain in a bronchus for years without causing any symptoms, and finally be expectorated. There are cases reported where foreign bodies, such as teeth, cherry-stones, etc., have been expectorated after having been ten and even nineteen years in the lungs.

Calcareous concretions are sometimes, but very rarely, formed in the lungs during chronic infections. They may be finally coughed up (lung-stones, pneumoliths).

Occasionally such concretions form about aspirated foreign bodies,

In other cases, the histologic examination shows they are made up of **necrotic** and calcified lung tissue (calcified tubercles). There are recorded cases where lung-stones in great quantities have been coughed up. **On** the chemical composition of lung-stones, see Stern.¹

Very rarely entire daughter cysts of pulmonary or hepatic hydatids **reach** the bronchi, and so appear in the sputum, in addition to microscopic constituents of the echinococcus (Fig. 271). Hair and teeth are sometimes found in the sputum following the perforation of a dermoid cyst of the mediastinum into the bronchi.

MICROSCOPIC EXAMINATION OF THE SPUTUM

In many cases this purpose can be satisfactorily accomplished by placing a small particle of the sputum upon a slide and then pressing down with a cover-glass. To recognize some of the constituents, the specimen must first be treated with reagents and stains (see later). The sputum should, however, first be examined just as expectorated. This process is frequently neglected. The presence of fungi or of crystals in the sputum, the nature of many cellular elements, etc., can be recognized only in such a fresh preparation, or, at least, much more easily recognized there.

Most sputa consist microscopically of a groundwork of mucoid material of indefinite structure in which pus-corpuscles are reembedded. The number of the latter determine the more or less purulent nature of the sputum. The character of these corpuscles varies considerably. Their size is from 7 to 10 μ . They are more or less granular. The granules consist partly of protein material (neutrophilic, rarely eosinophilic, granules; see Examination of the Blood, Leukocytes), partly of fat, partly of extraneous debris, identical with that of so-called lung epithelium (see below). Bacteria are also found inclosed in leukocytes, especially pneumococci. Like polymorphous leukocytes, from which they originate, these pus-corpuscles usually possess one irregular nucleus or several nuclei. In stained preparations (hematoxylin) the nuclear substance never appears as a vesicle, but is compact. (For the presence of eosinophilic mononuclear cells see p. 708 et seq.)

Epithelial cells are also found in sputum. They differ from pus-corpuscles in exhibiting a single, rather large vesicular nucleus. Various types of epithelium are found in the sputum. Their demonstration and recognition are of especial importance for determining the origin of a catarrhal expectoration. First of all, there is *squamous epithelium*, derived from the mouth, the pharynx, and a portion of the larynx, especially the true vocal cords (Fig. 276, *i*). There is *cylindric epithelium* (Fig. 276, *f, h*), derived from the deep-seated bronchi or from the nose, and represented by beaker-shaped and ciliated cells, although, of course, many of the latter have lost their cilia. They are rarely very numerous, except perhaps in a fresh bronchial catarrh. In the latter stages of catarrh they are almost completely supplanted by leukocytes.

Besides epithelium derived from the upper portion of the respiratory tract, there is the so-called *pulmonary* or *alveolar epithelium* (Fig. 276, *a, b, c*). These are oval cells, 20 to 50 μ in diameter, with one or several

¹ Deut. med. Woch., 1904, No. 39, and Carlyon, Brit. Med. Jour., 1890, ii, p. 1474.

nuclei and various substances inclosed within them. The latter consist of: (a) normal lung pigment, i. e., carbon (Fig. 276, a); (b) fat; (c) so-called myelin granules or drops, which are pale, irregular bodies of considerable size, showing concentric layers, and resembling the myelin globules of the central nervous system (see below as to their origin); (d) granules or scales of brown or yellow pigment, in all probability derived from blood-pigment (heart-cells; Plate 8, Fig. 3); (e) hematoidin crystals. The same cell may inclose a variety of inclusions. We do not know whether these cells, as claimed by Bizzozero, are derived exclusively from the epithelium of the pulmonary alveoli, or whether some of them may not be cells from the epithelium of the upper air-passages, or mononuclear leukocytes, enlarged by their contents.

Fig. 276.—Different morphologic elements of the sputum: a, b, c, Pulmonary or alveolar epithelium—*a*, with normal lung pigment (carbon); *b*, with fat-globules; *c*, with myelin granules or drops; *d*, particles of pus; *e*, red blood-corpuscles; *f*, cylindric beaker-shaped bronchial epithelial cells; *g*, free myelin granules; *h*, ciliated epithelium of different kinds from the nose, altered by coryza; *i*, stratified epithelium from the pharynx (after Bizzozero).

The character of the epithelial cells found in the sputum makes it possible to locate the portion of the respiratory tract from which the microscopic specimen was originally derived.

The myelin drops or granules above mentioned are often found free in the sputum. According to the investigations of A. Schmidt, they should be considered a product of normal secretion of the mucous membrane of the respiratory system. They make up the larger part of the *morning sputum*, which is swallowed by the majority of people. Chemical examinations by A. Schmidt and F. Müller have shown that the myelin of sputum consists largely of protagon, with which is mixed a small amount of cholesterin and lecithin.

If "heart-cells" occur in large numbers in the sputum, we are justified in assuming definite anatomic changes in the lung. These cells are filled with yellowish-brown pigment-granules. (See Plate 8, Fig. 3.) They have been called the "cells of heart disease," because they are found in the sputum in brown induration of the lung from cardiac lesions, especially those of the mitral valve. They are of real diagnostic importance in this condition if found in considerable numbers for a con-

siderable length of time without the existence of an infarction or of pneumonia. In the sputum of the two latter conditions these cells are also found as well as after hemoptysis. Their origin is explained as due to these cells having engulfed the remains of red corpuscles extravasated into the alveoli. Sputum containing many of these cardiac cells may sometimes appear slightly reddish brown.

Whenever the bloody character of a sputum is doubtful, a microscopic examination will usually determine the presence of the red corpuscles. They may have preserved their normal appearance, or they may be altered in various ways. They may disintegrate into distinct and separate accumulations of hemoglobin, and, later on, become amorphous or crystalline hematoidin, or sometimes the coloring-matter may be entirely dissolved.

Wherever lung tissue is considerably destroyed by any pathologic process, elastic fibers are apt to be found in the sputum. They form the resisting portion [the framework.—Ed.] of the pulmonary parenchyma

Fig. 277.—Elastic fibers from the sputum (after Bizzozzo).

(Fig. 277). Their presence in the sputum proves beyond a doubt the occurrence of some destructive process in the lungs, hence their importance in the early diagnosis of tuberculosis of the lungs before the tubercle bacillus was discovered. Even now the presence of elastic fibers may decide the diagnosis if we are unsuccessful in our search for tubercle bacilli. Elastic fibers are also found in pulmonary abscess and gangrene in greater or less number according to the rate of disintegration.

The fibers can usually be detected if a thin layer of fresh sputum be examined microscopically. If they are so scarce that they cannot be found in this way, the following procedure is recommended: About 10 cc. of sputum are boiled in a small porcelain dish with an equal quantity of 10 per cent. KOH. The mixture should be well stirred during the boiling. When it becomes homogeneous, it is diluted with about four times as much water, well shaken, and then centrifugated or allowed to stand in a pointed glass. If any elastic fibers be present, they may be picked up from the sediment with a pipet and then examined under

the microscope. After subjecting elastic fibers to KOH, they are usually somewhat less sharply outlined and slightly swollen.

When present in considerable quantity, they are easily recognized by their alveolar arrangement (Fig. 277, b). Beginners are liable to confuse isolated elastic with vegetable fibers, but most of the latter have a large diameter, and are much less plainly wavy. A beginner might be confused by the resemblance which thread-like collections of bacteria, or even the mycelium of fungi, bear to elastic fibers, but a higher magnification or staining will readily differentiate them.

R. May has described a very convenient method of staining elastic fibers with orcin. The method is useful in doubtful cases. The technic will be found in May's original article.¹

Weigert has also given an excellent method for staining elastic fibers in sections by means of fuchsin. The author recommends its employment for the demonstration of elastic fibers in the sputum. The cover-glass smear is first dried, and then fixed with absolute alcohol or formalin. A few minutes will suffice for fixation if alcohol be employed. If formalin be used, the specimen should be left for an hour in a 4 per cent. aqueous solution of formaldehyd, and then washed off with absolute alcohol. The staining fluid is prepared as follows: Two hundred cc. of an aqueous solution of fuchsin (1 per cent.) and resorcinol (2 per cent.) are brought to the boiling-point in a porcelain dish; 20 cc. of liquor ferri sesquichlorati are then added, and the mixture constantly stirred and boiled for three to five minutes, when a muddy precipitate will form. The mixture is then cooled and filtered. The filter and the contained precipitate are dried, and again placed in the same porcelain dish, which will also contain some of the precipitate. Two hundred cc. of 94 per cent. alcohol should then be added, and the mixture boiled over a water-bath and constantly stirred. During this procedure great care must be exercised to avoid ignition of the vapor. The fluid is cooled, and enough alcohol is added to bring the amount up to 200 cc., after which 4 cc. of hydrochloric acid are added. The cover-glasses should remain in this fluid from twenty minutes to an hour, after which they are washed with alcohol, cleared in xylol, and finally examined in Canada balsam.

Dr. J. Bamberger, of Kissingen, has recently informed the author that he and L. Michaelis have used the Weigert stain, in the following way, for the determination of elastic tissue in the sputum, and have found it trustworthy: The sputum is pressed, and equally distributed between two slides, by rubbing them backward and forward on one another. Large amounts of sputum, and especially the suspicious looking portions, should be selected. A slide is then dried in the air and completely submerged, without fixation, in a Coplin jar filled with Weigert's fuchsin solution (see above). The 94 per cent. alcohol of the Weigert solution suffices for the fixation.

The preparation is left in the stain for one-half to three-quarters of an hour, is then gently washed with alcohol containing 3 per cent. of HCl, and put in a Coplin jar containing 3 per cent. HCl-alcohol until no more color is given off. It is then removed, dried in the air (heat makes the color fade), and examined in cedar oil with a low magnification. One can take large amounts of sputum, since absolutely nothing but elastic tissue is stained.

Some cases of incipient phthisis which otherwise can hardly be recognized may show the presence of elastic fibers.

It is a peculiar fact that in some cases of gangrene of the lung, but not in all, elastic fibers of the lung are absent in necrotic pieces of lung tissue, recognized microscopically as such. In such cases the elastic fibers have been destroyed by a trypsin-like ferment formed by bacteria which grow in the gangrenous tissue. Even then the author has always found them after a sufficiently thorough search.

Fragments of neoplasms of the lung which are sometimes seen in the sputum (p. 701) are best recognized in microscopic sections.

Crystals Observed in the Sputum (Fig. 278).—Crystals occur in the sputum almost exclusively when the latter has remained in the

¹ Deut. Arch. f. klin. Med., vol. lxxviii, parts 5 and 6, p. 427.

body for a considerable length of time. Crystals of fat or of fatty acids are most frequently found. They form long needles (a), sometimes free and sometimes grouped together in rosetts. They may be distinctly bent, and so perhaps may be mistaken for elastic fibers; but may be readily distinguished by the fact that they dissolve in potassium hydroxid or ether; or gently warming the preparation will melt the fat crystals and form drops of fat. Crystals of cholesterin (b), of leucin and tyrosin (c), are very rarely observed. They are formed chiefly in stagnating, putrid sputum. (See the figures on p. 605 et seq. for the identification of leucin and tyrosin.) Crystals of triple phosphate and of calcium oxalate (see Figs. 256, 257, and Fig. 254, p. 673) may be found in the sputum

Fig. 278.—Crystals in the sputum: a, Fat; b, cholesterin; c, c, leucin (balls) and tyrosin (needles); d, d, hematoidin (bilirubin) in rhomboids and needles; e, e, Charcot-Leyden crystals.

under similar conditions. Hematoidin crystals (Fig. 278, d) are found chiefly in the sputum of abscess and of perforating empyema. The blood-pigment in pulmonary hemorrhages is mostly changed in the interior of the cells to amorphous pigment (see Heart-failure Cells), and but very rarely forms hematoidin crystals. Charcot-Leyden crystals (e) sometimes occur in the sputum. They are colorless, elongated, double pyramids, and vary considerably in size. They also occur elsewhere in the body during life and postmortem (in tumors, in stools, in leukemic blood, in bone-marrow, and in the spleen). They are very brittle, and, therefore, frequently observed with their ends broken off. They are soluble in hot water, mineral acids, and alkalis, and are stained by eosin.

Fr. Müller and Gollasch discovered a peculiar relationship between Charcot's crystals and the presence of eosinophilic leukocytes in the sputum. According to Müller, often as much as 60 per cent. of the leukocytes in asthmatic sputum are eosinophiles. Curiously enough, these eosinophiles are generally mononuclear, as contrasted with the ordinary neutrophilic leukocytes of pus and the eosinophilic leukocytes of the blood. It therefore seems rational to assume that Charcot's crystals are products of the crystallization of eosinophilic cells. This assumption is supported by the fact that the crystals readily stain with eosin, and that they occur in leukemic blood. (See p. 833.) Nothing definite is yet known regarding the chemistry of Charcot's crystals. Schreiner demonstrated that the so-called "Böttcher's sperm crystals" could be obtained by drying spermatic fluid. They resemble Charcot's crystals in appearance, and are the phosphate of an organic base (spermin, Pöhl). Schreiner's idea that they are identical with Charcot's crystals is pretty generally accepted. But Cohn¹ claims that these crystals differ considerably crystallographically, and that they belong to a different system. Charcot's crystals, as shown by their transverse surfaces, belong to the hexagonal system. They are doubly refracting, like Böttcher's crystals, but, unlike the latter, have a hexagonal transverse section.

These crystals are chiefly, but not exclusively, found in the sputum in bronchial asthma, so that for some time they were regarded as the exciting cause of the attacks. The bronchial nerves were supposed to be irritated by the pointed crystals. The relation, however, is not constant enough to justify any such conclusion. Asthma frequently occurs without crystals, and crystals are often found in the sputum without asthma. It seems much more rational to assume that during the asthmatic paroxysm, an opportunity is furnished for the formation of the crystals from eosinophilic cells, owing to the stagnation of the secretion products of the bronchial mucous membrane. Curschmann's spirals are to be included among these same products. The fact that Charcot's crystals are found in asthmatic sputum chiefly after the expectoration has been interrupted for a considerable length of time would seem to favor this theory. When expectoration is free and abundant, the crystals are usually absent. Furthermore, Charcot's crystals are found very abundantly in the interior of Curschmann's spirals; and, when the latter are preserved in a moist chamber, crystals may form in spirals which were previously free from them.

Animal parasites, or fragments of them, are very rarely found in the sputum. Amebæ (*Amœbæ pulmonalis*), flagellata (*Trichomonas pulmonalis*), and infusoria are very uncommon in the sputa, and of little importance clinically. They have been found in the sputum of pulmonary tuberculosis and of other pulmonary affections

with cavities, as well as in Dittrich's plugs. (See p. 701.) Hooks, scolices, and bits of membrane of echinococcus may be found in the sputum in the rare cases where echinococcic cysts of the lung or liver perforate the bronchi. There is a disease in eastern Asia (Japan, China, Korea) which usually manifests itself by the occurrence of hemoptysis. It is due to the presence of a worm (*Distomum pulmonale*, recently named *Paragonimus Westermani*?) in the lungs. Its eggs (Fig. 279) can always (often in great abundance) be demonstrated in the expectoration. They are oval, of a brownish-red color, 0.08 mm. long and 0.056 mm. broad, and are surrounded by a cuticle. They are easily identified under the microscope. They also occur in animals.

Fig. 279.—*Distomum pulmonale* with embryo ($\times 225$) (after Nakahama-Leuckart).

They are oval, of a brownish-red color, 0.08 mm. long and 0.056 mm. broad, and are surrounded by a cuticle. They are easily identified under the microscope. They also occur in animals.

Vegetable parasites are of greater interest and importance, especially the bacteria; the fungi play a more subordinate part. In

¹ Deut. Arch. f. klin. Med., 1895, vol. liv, p. 514.

² Inouye, Zeit. f. klin. Med., 1903, vol. l, p. 120. Stiles and Hassall, Sixteenth Report of the Bureau of Animal Industry, 1899.

examining the sputum for vegetable organisms, we should always bear in mind that by far the majority are saprophytic in nature, *i. e.*, they develop in the sputum either outside of the body, or, if within the air-passages, only in the secretion, and exist there in a more or less harmless way. To determine whether vegetable organisms in doubtful cases are expectorated as such, or are due to contamination of the sputum outside the body, we should examine the sputum fresh immediately after it has been expectorated. There are, however, a number of bacteria which can be distinguished with so much certainty from accidental contaminations that their presence, even in an old sputum, is of diagnostic importance. This is especially true of tubercle bacilli and pneumococci.

In obtaining sputum for bacteriologic examination a number of precautions must be observed. Since it is usually desired to examine the secretion originating in the deeper parts of the respiratory tract rather than that coming from the mouth, the mucopurulent masses should be selected instead of the thin secretion, which largely consists of saliva. It is well to examine only such clumps as are expectorated in the presence of the physician. If this be done, it is easy to determine from the character of the expectoration whether the mass has originated in the bronchi, in the larynx, in the pharynx, or in the nose. In order to reduce bacterial contamination from the mouth to a minimum, the oral cavity should be thoroughly washed with water just before the expectoration. The sputum obtained after this precaution is received in a clean glass; if cultures are to be made, the glass receptacle should be sterile and provided with a lid, so that the sputum may be immediately covered.

DEMONSTRATION OF TUBERCLE BACILLI IN THE SPUTUM

Tubercle bacilli are often so numerous in the sputum that they may be found with ease in any particle examined (Fig. 280); but in cases which are doubtful clinically and where the diagnosis depends entirely upon the examination of the sputum, tubercle bacilli may be found only after prolonged search. If the sputum be absolutely homogeneous, we must prepare a large number of slides without any particular selection. If mucopurulent, we can save time by spreading the expectoration upon a black background, and then selecting for examination the larger purulent clumps and any very cloudy, friable, cheesy-looking particles. Tubercle bacilli are also found even in slightly turbid or pure glassy sputum, although much less frequently. Tubercle bacilli may be found in the initial hemoptysis, although the patient seemed perfectly healthy beforehand. It is, of course, advisable in such a case to select particles which are not pure blood, but which have a certain amount of mucous and purulent material admixed. In a fresh hemor-

Fig. 280.—Tubercle bacilli (after a photograph by Günther) ($\times 500$).

rhage from the lung, the more profuse the bleeding, the less chance of finding bacilli.

The recognition of the tubercle bacillus depends upon a special procedure by which they alone are stained. If unstained, they cannot be distinguished from other bacteria. The ordinary methods of staining bacteria are not suitable. A specimen is prepared by teasing a portion of the sputum to be examined, placing a small fragment of it or of the sediment (provided centrifugalization has been performed, see p. 713) upon a cover-slip, and then carefully spreading it. To obtain a uniform distribution, a second cover-slip is placed over the first, and the two then drawn apart with the fingers or forceps. Unless too much material has been used, a thin layer will be left upon each cover-slip, and this may be dried over an alcohol or gas-flame with a moderate degree of heat. Sputum may also be spread upon glass slides. It must then be *fixed* so that it will not wash off in the staining fluid. This is done by passing the slip rapidly through a flame three times. The principle of the special stain for tubercle bacilli depends upon the fact that these bacteria do not stain readily with the ordinary anilin colors, but that when they are once stained, they do not readily decolorize, even after the action of the strongly decolorizing mineral acids. An anilin dye which acts very intensely is selected; and for this purpose the ordinary basic anilin colors are the best, such as fuchsin or gentian violet, mixed with carbolic acid or with anilin. The directions for preparing this stain are given below. (See p. 711.) A few drops of the stain are dropped upon the cover-glass, and the latter held over the flame with a pair of forceps until the fluid steams. This process will stain the tubercle bacilli and all other organisms present.

The next step is to decolorize all the other organisms and any other morphologic constituents of the preparation. This is easily accomplished, because the tubercle bacillus holds the anilin colors with great tenacity. It is "acid-fast."¹ Some mineral acid is generally employed for decolorizing, most frequently nitric acid in some dilution or other, as mentioned below. The acid is allowed to work until the specimen appears entirely decolorized. This occupies a few seconds to a minute, according to the thickness of the preparation. If parts of specimens be too thick, we select only the thin places for examination.

After decolorizing, the preparation is washed in water. If any color remain, the acid must be renewed. It is sometimes necessary to alternate these two processes several times. The specimen is then mounted upon a slide with water or balsam, and examined with an oil-immersion lens and an Abbé condenser.² A much larger specimen can be prepared and examined directly with the oil-immersion lens by dropping some cedar oil upon the slide. Although this method is a very good one,

¹ See p. 712 in regard to the occurrence of tubercle bacilli which are not acid-fast.

² In balsam preparations the tubercle bacilli, as also other bacteria, almost always become decolorized in time, and in order to obtain a truly permanent preparation the author recommends that the stained smear be examined in water, after which it may be preserved by letting the water evaporate.

One edge of the cover-glass can be fastened to a slide with a drop of melted, hard, Venetian turpentine or colophonium, removed from the hard resin by means of a hot iron wire, or even with shellac. In the German clinics this method of dry preservation is considered the best for bacterial preparations as well as stained blood-smears.

it is not to be recommended, on account of the danger of scratching the **objective** by particles of mineral matter contained in the sputum. **Such** a dry preparation may be made upon the slide, but it should be **covered** by one large or several cover-glasses of the usual dimensions.

A counterstain after decolorizing aids in recognizing other micro-organisms or tissues in the specimen, and makes them form a contrast to the tubercle bacilli. Methylene-blue is well adapted for this purpose if the tubercle bacilli have been stained red. If gentian violet has been employed, Bismarck-brown and fuchsin are suitable counterstains. This second staining may be accomplished without heating. The counterstain should not be intense enough to obscure the tubercle bacilli.

Details in reference to the counting of tubercle bacilli will not be given, since the author can impute neither a diagnostic nor a prognostic value to such a procedure. The number of tubercle bacilli in a single preparation is dependent upon chance in the selection of the particle examined; and even when such chance is eliminated by the study of a large number of specimens, the prognosis and the gravity of the case are entirely independent of the number of tubercle bacilli in the sputum. For this reason he regards Gaffky's scale for the quantitative designation of the bacilli as valueless, and employs simply the terms "a few," "many," or "very many" tubercle bacilli.

Tubercle bacilli (Fig. 280, p. 709) are 1.3 to 3.5 μ long and 0.2 μ thick. They may, however, be 11 μ long. They are usually somewhat bent, often very markedly so. According to the method of preparation, they appear evenly stained, or, as a result of unequal distribution of the chromatin, beaded, consisting of stronger and weaker or unstained kernels ("streptothrix forms"). At times they form little clumps, in which the separate individuals lie criss-cross or parallel to one another. At times there are masses like an ear of corn or a brush. In certain cases, instead of the usual form, the "splitter" forms described by C. Spengler are found: kernel-shaped masses which betray their relationship to the tubercle bacillus only by the characteristic stain, and which have their analogy in the "splitter and kernel" forms of the non-acid-fast tubercle bacilli. (For the latter, see p. 712.)

Solutions for Staining Tubercle Bacilli.—1. A solution of fuchsin or gentian violet in saturated anilin water (Ehrlich). The latter is prepared as follows: 5 cc. anilin and 5 cc. absolute alcohol are mixed with 90 cc. distilled water, and if cloudy, filtered. The stain is prepared by adding 11 cc. concentrated alcoholic solution of gentian violet to 100 cc. of this anilin water.

2. A solution of fuchsin or gentian violet in carbolic water (Ziehl-Neelsen). One gram of fuchsin or gentian violet is mixed with 10 cc. of absolute alcohol and 100 cc. of a 5 per cent. solution of carbolic acid; or a saturated solution of fuchsin or gentian violet may be dropped into a 5 per cent. solution of carbolic acid until saturation takes place (formation of metallic sheen on the surface). These carbolic solutions have the advantage of keeping for a considerable length of time.

3. Czaplewsky¹ recommends the use of the following solution: One gram of fuchsin in 5 cc. acidum carbolicum liquefactum in a dish. Fifty cubic centimeters of glycerin are added, stirring constantly, and then diluted with 100 cc. of water. This solution keeps extremely well and does not need to be filtered.

Ordinary aqueous solutions without anilin or carbolic acid may be used (concentrated alcoholic stain dropped into water and prepared fresh each time). The stain is somewhat less intense. The other mixtures are preferable for diagnostic purposes.

¹ Hyg. Rundschau, 1896, No. 21.

4. The best decolorizing method is that of Czaplewsky, who employs Ebner's fluid, consisting of:

R. Acidi hydrochlorici,	
Sodii chloridi	2.5
Aquæ destillatæ	100.0
Alcoholis	500.0

Before the employment of this fluid the specimen is washed with water; the decolorization may be accelerated by treating the specimen alternately with Ebner's fluid and water. The advantage of this fluid is that the other acid-fast bacilli are decolorized by the contained alcohol and cannot be confused with tubercle bacilli, as was the case with the purely aqueous solutions of acids previously employed.

Gabbet's method of decolorizing and counterstaining simultaneously, which was formerly almost universally employed, is not to be recommended, since Gabbet's solution contains no alcohol, and consequently will not guard against the confusion above mentioned.

As, apparently, individual tubercle bacilli may be decolorized by a too intense acid reaction, one oftentimes has to use milder decolorizing methods. In such cases Koch's original method of staining will serve the purpose. This consists in staining the tubercle bacillus with alkaline methylene-blue, decolorizing and counterstaining the other elements with a concentrated watery solution of Bismarck-brown. The method of Grethe described for the urine depends on a similar principle (see p. 694), where, after staining with carbol-fuchsin, the decolorizing and counterstaining are accomplished by an acid-free concentrated alcoholic solution of methylene-blue.

As a still milder decolorizing method, one may use 2 per cent. lactic acid, or, according to Kühne, 2 per cent. hydrochloric acid-anilin¹ solutions. In the latter case, the preparation, stained with the Ziehl-Neelsen solution, is placed for a few seconds in a 2 per cent. solution of hydrochloric acid-anilin and then decolorized in alcohol. This method is recommended when one wishes to demonstrate, together with the tubercle bacilli, the cellular elements, generally but little regarded.

Although the question of the staining of tubercle bacilli was presumably concluded long ago, M. Hermann² has recently recommended with especial emphasis a method little used, as a rule, but for a long time found by him to be trustworthy. To it is attributed the advantages of rendering at times the determination of tubercle bacilli possible when other methods fail, and of showing entire and intact bacilli when other methods stain only granules or "splitters." Hermann's stain consists of two solutions, to be kept separately—a 1 per cent. solution of ammonium carbonate in distilled water, which serves as a corrosive, and a 3 per cent. solution of crystal violet or methyl-violet (6 B) in 90 per cent. alcohol. Three parts of the first (the corrosive) are mixed with one part of the second (crystal violet solution). The stain should be left on the smear for one minute, while the slide is warmed over a flame until steaming begins. Decolorize with 10 per cent. nitric acid in 95 per cent. ethyl alcohol.

This method is particularly good for sections, especially for the determination of tubercle bacilli in lymph-glands of inoculated guinea-pigs. For this purpose the sections are carefully spread out on the slide, let dry, stained just as the dry preparations, then dried on the water-bath, and, without the use of xylol, are mounted directly in Canada balsam.

ON THE OCCURRENCE AND DETERMINATION OF THE NON-ACID-FAST TUBERCLE BACILLI, WHICH ARE NOT DEMONSTRABLE BY THE ORDINARY STAINING METHODS

The noteworthy fact that occasionally, in exceptionally destructive cases of pulmonary tuberculosis, no tubercle bacilli can be found in the sputum, is explained in part, according to H. Much,³ by the fact that, together with the forms demonstrable

¹ See Borrel, Experimental Pulmonary Tuberculosis, Ann. de l'Inst. Pasteur, 1889, vii, p. 593.

² Ibid., 1908, No. 1, p. 921.

³ Berlin. klin. Woch., 1908, vol. xiv, p. 691.

by the ordinary old method (decolorizing with acid), there exist forms which resist this method of examination, but which can be determined by Gram's method. (See p. 715.) These forms, according to Much, are: (1) Gram positive, small, non-acid-fast rods, generally granular, and (2) granular masses which morphologically correspond to C. Spengler's "splitter" forms, but, unlike these, are non-acid-fast and Gram positive.

This writer determined the genetic relationship of these abnormal forms to the ordinary tubercle bacillus by transforming the one into the other, and, at the same time, by demonstrating the virulence of the unusual variety. From this it may be concluded that it is important to employ the Gram method where the ordinary methods of examinations of the sputum show no tubercle bacilli. As the usual varieties of the tubercle bacillus are also stained by Gram's, the most rational method would seem to be to examine each case first for tubercle bacilli by Gram's method, and, if this be positive, to decide by a second preparation whether or not one is dealing with the ordinary acid-fast variety.

THE DIFFERENTIATION OF TUBERCLE BACILLI FROM OTHER ACID-FAST BACILLI IN THE SPUTUM

Occurrence of Smegma Bacilli in the Sputum

Pappenheim,¹ in Lichtheim's clinic, found smegma or nearly related bacilli in a non-tuberculous affection of the lung. They closely resemble tubercle bacilli in their affinity for acid stains. Laab found similar bacilli on the tonsils, on the tongue, and in the coating about the teeth. They are so rare, however, that probably very few serious mistakes have occurred. In examining urine for tubercle bacilli these smegma bacilli are of considerable importance. To avoid any mistake, Pappenheim's method of staining should be employed. This colors the tubercle bacilli red and the smegma bacilli and related forms blue. Pappenheim recommends the following procedure: (1) Stain in carbol fuchsin, heat to boiling-point for a few moments; (2) pour off the excess of carbol-fuchsin; (3) decolorize and counterstain, without washing, with the following solution, pouring it slowly three to five times over the preparation and allowing it to run off: One part of corallin is dissolved in 100 parts of absolute alcohol, and methylene-blue added until saturation (a considerable amount is necessary for this purpose); 20 parts of glycerin are then added; (4) wash quickly with water, dry, and mount. Duration of entire procedure, three minutes.

Confusion may be avoided by decolorizing the specimen stained in carbol-fuchsin with Ebner's fluid, as described above; or with Grethe's method (see p. 694), in which decolorization and counterstaining are accomplished by an alcoholic solution of methylene-blue and without any acid.

SEDIMENTATION OF TUBERCLE BACILLI

If the tubercle bacilli in a specimen of sputum be scarce, the examination may be facilitated by diluting the sputum and then centrifuging the mixture. This can best be accomplished as recommended by Biedert-Czaplewsky. One to 2 cc. of sputum are placed in a test-tube with six to eight times as much 0.2 per cent. solution of sodium hydroxid, shaken immediately, and then boiled once. After cooling, a few drops of a 1 per cent. alcoholic phenolphthalein solution, which colors the watery fluid a dark red, is added, 10 per cent. acetic acid is then added, drop by drop, until the color disappears. The fluid, if watery enough, is then centrifuged or allowed to settle; if not thin enough, it is first diluted with water. The resulting flocculent residue is used for making a dry preparation after first adding some of the original sputum, so as to make the layer stick, though this is rarely necessary. To determine the other micro-organisms which may be contained in the sputum, an antiseptic, for instance, an equal volume of a 1 per cent. solution of carbolic acid, should be added, so as to prevent the growth of contaminating bacteria during the time consumed in settling if this method be adopted. Tubercle bacilli and other bacteria in the dilute sodium hydroxid above mentioned survive, and the tubercle bacilli will often be found, where they would be missed in the ordinary dry preparation.

Spengler's² method of making the sputum homogeneous by pancreatic digestion or by peptic digestion in acid solution so as to prevent decomposition, has

¹ Berlin. klin. Woch., 1898, No. 37, p. 809.

² Zeit. f. Hyg., 1894, vol. xviii, part 2.

no particular advantage over Biedert's original method, according to the data the author has been able to collect.

Ilkewitsch¹ recommends another method which is very useful for collecting tubercle bacilli in the sediment. This consists in stirring the sputum for some time with twenty times as much water, precipitating with acetic acid (mucin, nucleo-albumin), and then centrifuging.

THE DEMONSTRATION OF VERY FEW TUBERCLE BACILLI IN THE SPUTUM IMPROVEMENT IN METHOD OF SEDIMENTATION (See Appendix.)

Despite all the perfections in the technic for demonstrating tubercle bacilli in sputum, frequently, as is well known, they cannot be discovered even in cases of perfectly evident tuberculosis. Hence, Ellerman and Erlandsen, of Copenhagen,² began to study the physical factors influencing the various sedimentation tests referred to above. They found that most of the difficulties encountered arose chiefly because tubercle bacilli of very light specific gravity are not readily centrifuged from so viscid a fluid as sputum, but that these difficulties can be partially overcome by diluting the fluid in two stages, being careful, in the former, to obtain a sediment which includes the bacilli concentrated in a smaller volume. These principles were recognized and employed by Ilkewitsch. (See above.) The sediment of the first dilution, comparatively rich in bacilli, is again diluted and centrifuged. They present a series of experiments which show that their so-called double method is much more reliable than any of the previously described sedimentation methods. In the first step, the authors make use of autodigestion at incubator temperature, with the addition of Na_2CO_3 solution, but not of trypsin. As a sediment forms the liquid becomes very thin. The resulting sediment is now allowed to settle, then dissolved in a solution of caustic soda (as in the Biedert-Czaplewsky test, see p. 713), the solution centrifuged, and from its sediment the slide prepared. They obtain a positive result from twenty to thirty times more frequently by this method than with simple dry preparations. The particulars of the technic follow:

(1) One volume of sputum (10 to 15 cm.) is mixed with one-half volume 0.6 per cent. Na_2CO_3 solution in a stoppered measuring glass, and is kept at 37° C. in a thermostat for twenty-four hours.

(2) Most of the superficial liquid is decanted, and the rest centrifuged in a graduated centrifuge tube. The supernatant liquid is then poured off.

(3) Four volumes of 0.25 per cent. NaOH solution are now added to one volume of sediment, the mixture then carefully boiled and stirred.

(4) The boiled fluid is centrifuged and the preparation made from the sediment.

[The so-called "enrichment method" of treatment with antiformin promises to be of considerable value in examining sputa containing only few bacilli. It has been found³ that antiformin, which is a mixture of liquor potassæ chloratæ (Javelle water), one part, and sodium hydoxide solution, one and one-half parts, destroys all bacteria except the acid-fast varieties. The technic proposed⁴ is as follows: Mix the sputum with sufficient antiformin to obtain 25 per cent. of the reagent in the resulting solution; stand for twenty-four hours; pour off the supernatant fluid and examine the sediment for bacilli in the usual way.—Ed.]

EMPLOYMENT OF ANIMAL EXPERIMENTS FOR DEMONSTRATING TUBERCLE BACILLI IN SPUTUM⁵

When no tubercle bacilli can be found in the sputum microscopically, even after sedimenting, animal experiments may be resorted to for diagnostic purposes. They may also be employed in attempting to distinguish the tubercle bacilli from other acid-fast bacilli. A suggestive portion is washed repeatedly and rubbed up in normal saline solution, and 0.5 to 1.5 cc. of the fluid injected into the peritoneal cavity or the groin of a guinea-pig. The weight of the animal is recorded, and it is killed in four to six or ten weeks, according to the diminution in its weight. An examination is then made to ascertain whether tuberculosis of the abdominal organs has developed. Even after two or three weeks tubercle bacilli can be often demonstrated in the pus expressed from a tiny fistulous tract originating in a swollen

⁵ See Levy and H. Bruno, Deut. med. Woch., 1900, No. 9, p. 141.

and purulent lymph-node or from an ulcer at the point of inoculation or from an extirpated lymph-gland itself. Since the pseudotubercle bacillus produces similar lesions, it is necessary to prove that the organisms found are acid-fast. Sometimes the animals die in twenty-four to seventy-two hours, from an infection with pneumococci or streptococci. The experiment should then be repeated, after heating the sputum for ten minutes at 60° C., a temperature which will, according to the investigations of Forster and his pupils, kill all inflammatory organisms but not the tubercle bacilli.

To hasten the diagnosis of tuberculosis Bloch⁴ has recommended that injections be made subcutaneously into the guinea-pig's groin and that the inguinal glands be then squeezed firmly between the fingers. Tuberculosis in these glands should be demonstrable both macroscopically and microscopically in from nine to eleven days. For staining sections, Hermann's method (see p. 712) should be considered.

THE DEMONSTRATION OF OTHER MICRO-ORGANISMS IN THE SPUTUM

For the determination of micro-organisms in the sputum the direct microscopic examination of the fresh sputum, expectorated just previously in the presence of the observer, has a much greater value than the much overrated culture method. (See later, Examination of the Mouth and Pharynx, Diphtheria Bacillus.) Most pathogenic bacteria present in the sputum occur in small numbers from time to time, in the mouths of healthy individuals as perfectly harmless occupants, so that the culture can deceive by distorting the relative proportions of the bacteria present, and, on the other hand, many pathogenic organisms are not easily grown from sputum without further measures.

They may be demonstrated in dry preparations made very much in the same way as those for tubercle bacilli, stained with the same solutions and according to the same methods, except that the subsequent treating with the acid is omitted. After staining, the preparations are washed in water only. If the stain be then too intense, the preparation may be subjected for a very few moments to the action of alcohol. The latter will remove any of the precipitated stain and render the bacteria more distinctly visible. Most bacteria possess so great an affinity for fuchsin, gentian violet, and methylene-blue that heating is unnecessary. Cold preparations will stain bacteria sufficiently inside of a few seconds to a minute.

Gram's Method.—Some bacteria stain very intensely with Gram's method, while the other elements of the sputum are decolorized. A dried specimen is stained with anilin gentian violet and then washed with water; Lugol's solution¹ is then added drop by drop. The iodine solution is allowed to act upon the preparation from one to three minutes; it is then washed with absolute alcohol until entirely decolorized macroscopically. When no further color can be washed away, the specimen is dried, and then examined in cedar oil or xylol balsam. The nuclei and the body of the preparation will appear entirely decolorized or very slightly yellow, but the micro-organisms will be stained intensely blue or almost black. By subsequent counterstaining (Bismarck-brown or fuchsin ten times diluted, Ziehl-Neelsen's or Czaplewsky's solution) a capital contrast stain is obtained.

Beautiful specimens may also be obtained, according to Czaplewsky, if Weigert's modification of Gram's method be combined with a fuchsin counterstain. Czaplewsky

¹ Berlin. klin. Woch., 1907, No. 17.

² This solution consists of 1 part of iodine, 2 parts of potassic iodide, and 300 parts of water.

describes the procedure as follows: Stain for one minute in carbolic gentian violet (11 cc. of a concentrated alcoholic solution of gentian violet, 10 cc. of alcohol, 50 cc. of a 5 per cent. solution of carbolic acid, 50 cc. of distilled water); wash thirty to sixty seconds. Lugol's solution (iodin 1, potassium iodid 3, water 200); wash, dry, differentiate with anilin-xytol 2 in 10, to which has been added 1.5 per cent. of acetone; wash with xytol, dry, restain with carbol-fuchsin diluted up to 1 in 10 (see p. 711) for about one minute, during which time the specimen is warmed slightly. The specimen is then washed, dried, embedded in Canada balsam, and examined with the oil-immersion lens.

Staphylococci, streptococci, diphtheria bacilli, tubercle bacilli (if stained with heat), anthrax bacilli, bacilli of tetanus, and Fränkel's pneumococci stain with Gram's stain (Gram-positive bacteria); whereas typhoid, colon, influenza, and cholera bacilli, Friedländer's bacilli of pneumonia, plague, glanders, and the pertussis bacilli decolorize with Gram's stain (Gram-negative bacteria).

This property of decolorizing is only a relative one, for individuals of certain species, which, as a rule, are not stained by Gram's stain, may retain their stain, and vice versa. A great deal depends upon the intensity of action of the decolorization. Where mixtures of bacteria and not pure cultures are being treated, as in the examination of sputa, the question whether certain bacteria decolorize after Gram's stain can best be decided by subsequently counterstaining with a fuchsin solution diluted ten times. Bacteria which decolorize after Gram's stain will then be stained red, and the Gram-positive bacteria blue to black.

The demonstration of *Fränkel's pneumococci* in the sputum is of considerable diagnostic importance. They are usually elongated, lance-shaped cocci, generally arranged in pairs with their bases approximated.

They are surrounded by a faintly staining capsule, which in dry preparations usually does not stain at all. Fränkel's pneumococci have been shown to be the cause of croupous pneumonia. They must not be confounded with other diplococci found in the sputum, more especially with Friedländer's¹ so-called diplococci. The latter also possess a capsule, but they have nothing to do with the etiology of croupous pneumonia, although they may sometimes be present with pneumonia. Friedländer's cocci, when strongly magnified, are seen to be short, plump bacilli much larger than pneumococci. Cultural differences also exist, and Gram's

Fig. 281 —Fränkel's pneumococci (from a photograph by Fränkel) (\times about 800).

stain decolorizes them, but stains Fränkel's diplococci. W. Wolf has furnished us with a very useful double stain for Fränkel's diplococci. The dry preparation is first of all stained in anilin water saturated with fuchsin, and then placed one to two minutes in a diluted, transparent aqueous solution of methylene-blue. The cocci stain blue, the capsule rose color, and the body of the preparation a bluish red. [Staining with India ink brings out the capsule very plainly.—Ed.]

¹ [Friedländer's micro-organism is a species of bacillus belonging to the same group as the various species designated *Bacillus mucosus capsulatus*.—Ed.]

The diagnostic significance of pneumococci is limited, because the same organism may be found in the normal secretions of the mouth and in non-pneumonic sputum. It is identical with the organism of an experimental sputum septicemia of rabbits and mice. The pneumococci, however, are found in very small numbers in normal mouth secretions. According to modern views, any bacteria found in the body normally may, under certain conditions, acquire pathologic significance, so that we need not modify the etiologic importance of Fränkel's cocci in pneumonia.

In the saprophytic forms, the capsule formation, according to Kolle, is less pronounced than in the pathogenic.

Pneumococci are not always easily differentiated from streptococci, as they can grow in chains in excretions as well as in culture, and the pneumococcus and the streptococcus may both show lanceolate forms. The distinction is even more difficult, as the elongated form of the individual coccus, as well as the capsule, is not absolutely characteristic for the pneumococcus. They are frequently encountered among the ovoid-shaped streptococci, some with elongated form and vice versa; there occur among pneumococci perfectly round or ovoid forms. All this apparently depends upon the intensity of the growth. And, further, there are streptococci with capsules, the *Streptococcus mucosus*. In culture also the differences are often not distinct.

According to Levy,¹ one differential point between the pneumococcus and the streptococcus is that the former is decomposed in bile, or rather in a solution of sodium taurocholate, in contradistinction to the streptococcus. If 0.1 cc. of rabbit's bile or of a 10 per cent. solution of sodium taurocholate be mixed with 0.5 cc. of a bouillon culture of pneumococcus, the cocci are decomposed in from three to twenty minutes, and the culture is then sterile. The *Streptococcus mucosus*, which is closely related to the pneumococcus (if it be not identical with it), is the only streptococcus which behaves under these circumstances just as the pneumococcus.

With reference to the differences of hemolytic action, see p. 720.

The *influenza bacillus*² was described by R. Pfeiffer as the cause of the great epidemic of influenza in the early part of the nineties. It is of some diagnostic importance (Fig. 782).

It is a very small bacillus; is hard to stain; is sometimes arranged in pairs; is always found in fresh attacks of true influenza, and usually in very great numbers, free or included in the leukocytes. In parts of the sputum it may be obtained practically in pure culture. Pfeiffer obtained the best-stained specimens by allowing dry preparations to float five or ten minutes on a very dilute, pale-red solution of carbol-fuchsin. Influenza bacilli are only two or three times as long as they are broad. They rarely form threads. The ends are rounded off, and with faint staining will be somewhat more deeply colored than the center, so that they may resemble a diplococcus. This appearance may also be produced if two short rods lie side by side. Influenza bacilli have no capsule and are not mobile. They do not stain by Gram's method. Influenza bacilli can be cultivated only on media containing hemoglobin, a fact which may serve to differentiate them, for instance, from the colon bacillus. An appropriate medium can be easily prepared by spreading a little blood with the infected material upon the surface of ordinary agar. In regard to the character of the colonies and the results of animal inoculations, we must refer to Pfeiffer's original work.

In late years, at least in Switzerland, the influenza bacillus has hardly ever been found in the so-called attacks of influenza. On the

¹ Virchow's Arch., 1907, vol. clxxxvii.

² Zeit. f. Hyg., 1893, xiii, p. 357 et seq.

contrary, the causative agent has apparently been the pneumococcus of Fränkel, for it has been found in the sputum of these cases frequently in great numbers, even when there were only signs of bronchitis and without pneumonia. If the influenza observed in the nineties be

Fig. 282.—Influenza bacilli ($\times 1000$) (after Pfeiffer).

regarded as a specific disease produced by the influenza bacillus, which does not seem to the author to have been absolutely established, it might be well to limit the term influenza to cases with the influenza

Fig. 283.—Saprophytic bacteria of the mouth, from the gums. The large rods are *Leptothrix buccalis* (\times about 800) (after Fränkel).

bacillus, and to cease applying this name to pneumococcic infections and common catarrhal conditions.

Has it then become unfashionable to diagnose a coryza or a bronchitis, or, if one wishes to diagnose etiologically, a catarrhal coccus

(meningococcus) coryza, a pneumococcus bronchitis, pneumococcus tracheitis, or pneumococcus pharyngitis? Is catching cold dismissed as a cause of transient illness attended with fever? Who has dismissed it? With what right? Has it become a menace to one's reputation to diagnose such things, and is it scientific, according to the ideas of laymen, to allow the nebulous phantom of influenza suddenly to loom up on all sides? Is it right and necessary to console a tuberculous patient who has fever with the diagnosis of influenza, instead of with an explanation that his illness has proceeded to a febrile stage, and with the prediction that the fever will again disappear?

Leptothrix buccalis and other saprophytic bacteria are often observed in fresh sputum, for they grow in the normal mouth and there become mixed with the expectoration (Fig. 283). They may multiply in the lung under pathologic conditions and appear very abundantly in the sputum, especially in putrid diseases of the lung. They do not seem to have any actual pathogenic significance, except that they may play a

Fig. 284.—*Streptococcus pyogenes* (\times about 800) (after Fränkel).

Fig. 285.—*Staphylococcus pyogenes aureus* (culture) (\times 1000) (after Weichselbaum).

very considerable part in the putrid decomposition of secretions. The bacillus known as *Leptothrix buccalis* or *pulmonalis* may be easily recognized by its size and shape and its peculiarity of frequently (not always) staining blue with Lugol's solution. This latter peculiarity seems to depend upon the starch content of the nutrient medium.

The *Micrococcus tetragenus* may be found in the sputum in various conditions: in bronchitis, in cavities of the lung especially, and sometimes in the saliva of healthy people. It is a Gram-positive organism. The tetrads are usually isolated, and often surrounded by a colorless or faintly stained capsule. They can be distinguished from sarcina groups in being composed of one layer of four individual organisms, and not of a cube, like the sarcinæ(8). It is pathogenic for animals, white mice, and guinea-pigs, and may also produce suppuration in man. Very possibly it aids the tubercle bacillus in destroying the lung tissue in phthisis. It grows readily upon the ordinary nutrient media and does not liquefy gelatin.

The same possibility applies to the *streptococci* and *staphylococci*, which are (Fig. 284) found not infrequently in very great numbers in tuberculous sputum.

With regard to the differentiation of streptococcus and staphylococcus, it may be remarked that a distinction is not always possible in the secretions, because the streptococcus does not always form chains, and the staphylococcus can, under circumstances, also form isolated, generally short, chains of three or four individual

cocci. On the other hand, the differentiation by culture is always easy. (See the many text-books on Bacteriology.)

Pathogenic, i. e., the virulent, streptococci generally form longer chains ("Streptococcus longus") than the avirulent. According to Mandelbaum,¹ the different varieties of streptococcus can be differentiated on blood agar (2 parts blood and 5 parts agar), since the markedly pathogenic forms ("Streptococcus longus") decolorize the media about them by their hemolytic action, while the less pathogenic "Streptococci mitior" ("S. viridans") and the "Streptococcus saprophyticus" do not do this. The author observes that the green coloration of the blood media attributed to the non-hemolyzing streptococci serves merely for contrast.

With reference to the distinction between pneumococci and streptococci see p. 717. On solid blood media the former behave as Streptococcus mitior, i. e., they are non-hemolytic.

The *Micrococcus catarrhalis* is almost always found in the nasal secretion in rhinitis, and is quite frequently observed in the sputum from the lungs. It differs from the ordinary staphylococci by its much larger size, by its decolorization by Gram's method, and by its frequent intracellular location. With the exception of its larger size, it closely resembles the gonococcus, and, like the latter, as well as like the ordinary staphylococcus, is frequently grouped in pairs as a diplococcus, the contiguous sides of the paired cocci appearing distinctly concave.

More and more proof accumulates that the micrococcus is identical with the meningococcus intracellularis.

Fig. 286.—Bordet's bacillus of whooping-cough.

Bordet's Bacillus of Whooping-cough.—Bordet² found in the sputum of whooping-cough a specific bacillus, short, Gram negative, and colored more strongly on the ends (Fig. 286). He cultured it, and demonstrated by agglutination and complement deviation experiments that it was the specific cause of whooping-cough. These findings have been confirmed by Arnheim.³ Cultures do not grow on ordinary nutrient media, but only on faintly acid media, poor in nutrient material, with a substratum of ascitic fluid or blood, which hinders the growth of most saprophytic and pus-forming organisms. Upon his culture-media it grows at first very sparingly and almost invisibly and only abundantly by transplantation. The sputum of the early stage of the disease serves best for cultivation. Bordet prepares his media as follows: To 200 cc. of water, containing 4 per cent. of glycerin, is added 100 gm. of potato, cut in slices. This is cooked in an autoclave, the fluid decanted, and a glycerin-containing potato extract is thus obtained. Fifty cc. of this extract, 150 cc. of a 0.6 per cent. sodium chlorid solution, and 5 gm. of agar, are let digest in the autoclave. The fluid is filtered into test-tubes while still warm, 2 to 3 cc. to each tube, and then sterilized. Some blood from a guinea-pig, or better from the human,

¹ Zeit. f. Hyg., vol. lviii, part 1.

² Ann. Pasteur, 1906, No. 9, and 1907, No. 9.

³ Berlin. klin. Woch., 1908, No. 31.

is obtained and defibrinated under aseptic precautions, and an equal amount of the defibrinated blood is added to the agar in each test-tube, shaken up, and the tubes are then placed on a slant and allowed to cool. This medium serves for the culture of other delicate micro-organisms besides the whooping-cough bacillus, such as the gonococcus, meningococcus, influenza bacillus, and others, which are easily overgrown by saprophytes on ordinary media.

In recent years bubonic plague has occasionally occurred in regions in which the disease is not endemic, and the *pest bacillus* must consequently be described. Although bacteriologic laboratories will usually make the bacteriologic diagnosis of bubonic plague, it will occasionally happen that the physician will be forced to make his own diagnosis, and in such cases he should be familiar with the method of bacteriologic examination. This is particularly necessary in the cases in which the lungs are affected, since the clinical course of the disease may then almost exactly correspond to that of an ordinary catarrhal or croupous pneumonia. Enormous quantities of pest bacilli may be found between the red blood-corpuscles in the hemorrhagic sputum of such cases. The pest bacilli may also be present in the expectoration in the ordinary bubonic plague. Czaplewsky describes them as follows: They are usually short rods with rounded ends, their length being two to three times greater than their breadth. They are occasionally so short, however, that they resemble cocci. They are readily stained, the poles appearing darker than the central portion, which may be pale or even colorless. (See Fig. 289.) This polar

Fig. 287.—*Micrococcus tetragenus* (X about 800) (after Fränkel).

Fig. 288.—*Aspergillus fumigatus* (X about 350) (after Fränkel)

stain may be most beautifully obtained by staining the bacilli for a half-minute in dilute borax methylene-blue (stock solution with 2 per cent. methylene-blue and 5 per cent. borax). The pest bacilli are decolorized by Gram's method. They are non-motile. For methods of cultivation the reader is referred to the official communications of the German government for the bacteriologic diagnosis of bubonic plague (published by J. Springer, 1902), and to the works of Kossel and Overbeck (from the Imperial Health Office, 1901, Part 1).

In pulmonary glanders the *Bacilli mallei* may be found in the sputum. They cannot be sufficiently identified by microscopic examination, but for identification require to be grown in cultures, and particularly to be inoculated into the lower animals. They are of about the same length as tubercle bacilli, but are thicker and have rounded ends. They are non-motile, and are decolorized by Gram's method. Particularly characteristic is an alkaline potato culture, which, after two days at a temperature of 37° C., presents slimy, drop-like colonies, varying in color from honey yellow to copper red, about which the potato is darkly stained. Kolle states that other bacteria, e. g., *Bacillus pyocyaneus*, may exhibit a similar growth. *Bacillus malleus* grows upon most slightly alkaline nutrient media, and best between 33° and 37° C. Experiments upon animals are performed as follows: A guinea-pig is inoculated subcutaneously with the suspected material. From the resulting swollen glands a tiny piece is excised and introduced into the peritoneal cavity of another male guinea-pig. Upon the second or third day this second animal develops a characteristic orchitis produced by glanders. Since other bacteria may also pro-

duce an orchitis, the morphologic and cultural characteristics of the *Bacillus mallei* must also be taken into consideration.

In the so-called wool-sorters' disease, which is nothing else than pulmonary anthrax, the *Bacillus anthracis* may be found in the sputum. (See Fig. 309.) These bacilli are easily stained, and may be readily recognized by their size (length 5 to 10 μ , breadth 1 to 1.5 μ). The ends are frequently slightly concave, giving rise to the so-called bamboo form. They liquefy gelatin and grow out into long, waving chains, which develop endogenous, highly refractile spores. Mice quickly die after the subcutaneous inoculation of anthrax bacilli; the edematous fluid at the site of the inoculation and the blood contain large numbers of the bacilli.

The occurrence of *typhoid bacilli* in the sputum is of very slight diagnostic importance. It has been particularly observed in the pneumonia of typhoid fever. The author himself has seen a case of typhoid in which a serous pleuritic exudate containing large numbers of typhoid bacilli perforated into the respiratory passages and was expectorated.

The presence of *sarcinae* in the sputum possesses a certain amount of interest. They resemble and are often confounded with the *Micrococcus tetragenus*, but are considerably larger. (See p. 719.) They are very rarely found in the sputum. True *sarcinae* are best seen in unstained preparations. Fig. 201, c and d, gives some idea of their appearance. It has not as yet been definitely settled whether or not the

Fig. 289.—Pest bacilli in a smear made from a bubo; stained with methylene-blue (Kolle).

sarcinae of the stomach (described above) are identical with those of the lung. *Sarcinae* have been found in the sputum, chiefly in gangrene of the lung, but also in tuberculosis, bronchitis, and pneumonia (pneumonomycosis *sarcinica*). *Sarcinae* should probably be considered saprophytic, especially when we consider their occurrence in all these conditions. The same type of *sarcina* may develop in the mucous membranes of the mouth and pharynx of debilitated patients, producing the grayish spots of pharyngo- or stomatomycosis, and from this source may be found in the expectoration.

Yeast fungus has also been observed in sputum, although in most cases it is an accidental contamination, yet, from a case recorded by Busse,¹ it is not to be denied that it can have pathogenic significance. In these cases there are moderately small yeast-cells, 8 μ in diameter, strongly refractile, becoming clearer on the addition of dilute soda solution.

It has recently been found that various kinds of molds belonging to the genus *Aspergillus* (Figs. 288 and 290), or perhaps to the genus *Mucor*, may develop in the lung; but practically only when there is some coexisting destructive cavity formation, with a few exceptions described by Saxer and others. The cavities where these molds have been found are almost exclusively devoid of odor. The relation of the molds to putrefactive bacteria observed outside of the body would seem to

¹ See Kolle and Wassermann, Handb. d. path. Microorg.

make it probable that the constant antagonism between these two kinds of organism continues in the interior of the body, so that the aspergilli protect a pulmonary cavity from putrefactive bacteria; and, conversely, the saprophytic bacilli found in the majority of cases protect the lung from becoming overgrown with some mold. Molds only very exceptionally invade an otherwise healthy lung; but if they once settle there, they aid in the general destruction, as is definitely proved by the examination of the pathologic processes. Very likely they may even displace the primary pathogenic bacilli. Cases where *pneumomycosis aspergillina* or *mucorina* seems

Fig. 290.—*Aspergillus fumigatus* of the lung (partly schematic): a, a, a. Mycelium of aspergillus in roset-like rays; b, sporangium ($\times 285$) (after Weichselbaum).

to be primary can be explained in this way. It has not been proved that they ever occur primarily, and although the spores of aspergillus are everywhere, yet *Aspergillus* mycosis is extremely rare. The only diagnostic criterion differentiating *pneumomycosis aspergillina* or *mucorina* from ordinary bronchitis, phthisis, etc., is the demonstration of the molds in a fresh specimen of sputum, or in a dry specimen stained with saffron or thionin (Figs. 288 and 290) (mycelium, spores, conidia). The varieties, as a rule, can be separated only by culture (sterile moist bread, see special text-books).

Fig. 291.—*Oidium albicans* ($\times 400$) (after Bizzozero).

Up to the present time there have been described, to the author's knowledge, only four cases of *mucor* mycosis of the lung,¹ all of which have to do with different species of *mucor*. More often there are aspergillus infections, in which the *Aspergillus fumigatus* is concerned. With regard to the clinical condition, the reader is referred to Sticker's article, "Mold Infections of the Lung," in Nothnagel's System, 1900.

In rare cases the *Oidium albicans*, another mold, may develop in the lung. It is best detected in fresh, unstained preparations of sputum (Fig. 291). It develops much more frequently upon the mucous membranes of the mouth, pharynx, and esophagus than in the lung. From any one of these sources it may be found in the sputum (Fig. 291). It shows best in unstained preparations.

¹ See Emerson, Clinical Diagnosis, 1906.

The rare cases of *actinomyces*, the disease caused by *ray fungi*, which infect the human lung, should be mentioned. Their course clinically is similar to that of tuberculosis of the lung, except that instead of the tubercle bacillus, this fungus is found. The characteristic yellowish or grayish-green granules (the size of a poppy seed) of actinomyces can generally, but not always, be recognized with the naked eye (Fig. 292). The microscopic examination is not always decisive either. In some cases the microscopic rosetts of the fungus are to be found; in others only the branch-

Fig. 292.—Young actinomyces granule (prepared section). In the middle, the mycelium; on the edge, the clubs, which become much thicker with maturity. From a preparation stained by Gram's method ($\times 530$) (after Weichselbaum).

ing threads staining by Gram's method (Fig. 292), with or without club-like ends. Occasionally even coccus-like structures are found, the actinomyces belonging to the pleomorphic class of streptotriches. Generally speaking, microscopic elements of this sort make the diagnosis of actinomyces very probable; still, it is wise to follow Silberschmidt's¹ advice, and prepare aërobic and anaërobic bouillon and agar cultures for the purpose of differentiation. This fungus grows anaërobically.²

Fig. 293.—Actinomyces from a tumor of the lower jaw of a cow: 1, An entire granule ($\times 500$); 2, 3, 4, 5, 6, 7, different forms of clubs; 8, 9, 10, round elements ($\times 1000$) (after Mace).

Streptothrix of the lung is closely related to the last-named fungus, and in the sputum of an infected individual similar granules are to be found. The threads may branch and resemble those of actinomyces; they are also Gram positive. Clubs rarely occur. It grows, however, aërobically.

CHEMICAL EXAMINATION OF THE SPUTUM

ALBUMIN IN THE SPUTUM

Wanner¹ calls attention to the diagnostic importance of the presence of albumin in the sputum. The greater the quantity of albumin in the expectoration, the more marked will be the inflammatory process to which the sputum owes its origin. From a practical standpoint, Wanner notes that the sputum of a simple chronic bronchitis is always practically free from albumin, while that of pulmonary tuberculosis is usually characterized by a distinct quantity of albumin.

To demonstrate this albumin, a measured quantity of the expectoration is placed in a glass flask with a 3 per cent. solution of acetic acid, and violently agitated until the mucus is decomposed. The mixture is filtered, and the residue is washed with 3 per cent. acetic acid. The strongly acid filtrate, which contains the albumoses and the albumin of the sputum without the mucin, is now treated with sodium hydroxid until it is only slightly acid in reaction. If necessary, concentrated saline solution may be added, after which the albumin may be coagulated by boiling. The albumin may also be precipitated from the strong acetic acid solution by potassium ferrocyanid. In either case the resulting precipitate gives a qualitative and a quantitative test for the amount of albumin in the sputum. Esbach's method, as applied to the urine (see p. 615 et seq.), may also be employed for an approximate quantitative estimation of the amount of albumin.

Wanner estimates the mucin content of the sputum from the glucosamin split off from the mucin by boiling with dilute acid. The sputum is first shaken up with two volumes of alcohol, filtered through hardened filter-paper, and washed with alcohol. The precipitate is then boiled for three hours with 10 per cent. HCl in a flask with a return condenser, cooled, neutralized to a very weak acid reaction, precipitated with phosphotungstic acid, in order to separate the biuret reacting bodies, and then with alkaline copper solution; the reducing action of glucosamin is estimated qualitatively and finally quantitatively. Glucosamin has nearly the same reducing power as glucose. Mucin contains 33.6 per cent. glucosamin.²

The color examination of sputum by means of stains should here be described. This procedure was inaugurated by A. Schmidt, who stained sputum with Biondi's triple stain. Zenoni's method is simpler. The sputum is spread in a thin smear on a cover-glass or slide, hardened in alcohol for at least a quarter of an hour, and stained with a half-saturated watery solution of safranin. When examined on a white background, the mucin is stained yellow and the albumin red.

CHIEF CHARACTERISTICS OF THE MOST IMPORTANT TYPES OF SPUTA

CATARRHAL OR BRONCHITIC SPUTUM

Ordinarily, catarrhal sputum is essentially mucopurulent without any other admixtures. In the beginning of an acute bronchial catarrh the mucus usually predominates and the sputum is scant. After a few days the expectoration becomes more abundant, less tenacious, and considerably more purulent, the general discomfort at the same time lessening. As recovery progresses, the amount of pus diminishes with the diminution in the quantity of expectoration, until the sputum disappears entirely. In chronic bronchitis the nature of the expectoration may vary considerably, being at times more, at times less, purulent. Patients usually feel more comfortable when the sputum is fairly abundant; whereas the discomfort is increased when the secretion becomes excessive or if it cease entirely.

¹ Deut. Arch. f. klin. Med., 1902, vol. lxxv, parts 3 and 4.

² See also the work of F. Müller, Zeit. f. Biol., vol. lii.

SPUTUM IN FIBRINOUS OR CROUPOUS BRONCHITIS

The sputum of croupous differs from that of ordinary bronchitis. Fibrinous coagula in the shape of casts of the bronchi appear in the sputum from time to time, usually associated with more or less blood. Charcot's crystals are very frequently found in these formations. The larger coagula are apt to be expectorated with very severe paroxysms of coughing, which have usually been preceded by more or less dyspnea. Hochhaus has shown that similar formations composed of mucus may occur in this affection.

SPUTUM IN ORDINARY PULMONARY TUBERCULOSIS

Macroscopically, this cannot be absolutely distinguished from simple catarrhal sputum. Any type may be present, from a purely mucous to an almost purely purulent sputum. In well-advanced ulcerative types of phthisis the amount of pus is usually considerable. Friable, opaque white particles always make one suspect tuberculosis. The sputum of tuberculous patients frequently has a very bad odor, especially if there be cavities with stagnating contents. A positive diagnosis of tuberculosis can be made only when the tubercle bacillus is found; but if all other destructive processes of the lung can be eliminated, elastic fibers are very suggestive. The abundance of these morphologic elements by no means indicates the severity of the case. There are very severe cases of tuberculosis of the lungs where no bacilli and no elastic fibers can be found. These are frequently very malignant and acute cases, where the constitution is undermined before disintegration of the pulmonary infiltration begins, or cases where miliary tuberculosis is alone responsible for the grave symptoms. Again, if the catarrhal secretion be profuse, which is common, especially in unfavorable cases, the number of tubercle bacilli in the sputum will seem few on account of the dilution. On the other hand, we not uncommonly find tubercle bacilli and elastic fibers in the sputum of early tuberculosis of the lung, where physical examination reveals no abnormal signs or only slight ones. The significance of tubercle bacilli in cases of this sort is of very decided importance. Naturally, then, any variation in the number of elastic fibers or of tubercle bacilli which are present in the same individual cannot be interpreted, in and of itself, as indicating any marked change in the course of the disease. In judging the value of therapeutic measures, such false interpretations have frequently, although improperly, been applied.

SPUTUM IN ACUTE MILIARY TUBERCULOSIS

This presents the characteristics of an ordinary catarrhal sputum, and if not complicated by ulcerative phthisis, is without bacilli. There may be no sputum at all. (See p. 534 in regard to the occurrence of tubercle bacilli in the stools in this affection.)

SPUTUM IN CROUPOUS PNEUMONIA

The characteristic feature of the sputum of croupous pneumonia is its blood-content. The blood is usually uniformly mixed in a glairy menstruum, the sputum appearing almost transparent and homogeneous. Not infrequently, however, particles of sputum free from blood alternate with hemorrhagic streaks and spots or with considerable quantities of almost pure blood. In many cases the original color of the blood is almost completely preserved; in others, especially when the blood is uniformly mixed with the glairy menstruum, the blood-pigment is modified to a yellowish or brownish red, as previously described (*rusty sputum*, *sputa crocea*). Blood-corpuscles can be recognized microscopically in any pneumonic sputum, although they are almost completely laked out. The peculiar change of blood-pigment producing green and yellow sputa has been already considered (p. 697). Pneumonia not infrequently gives rise to jaundice (p. 42), in which case the sputum is apt to be yellow or greenish and show Gmelin's reaction (p. 575). Fibrin coagula are not uncommonly found in the sputum of pneumonia; we have already considered (p. 702) their peculiarities and the method of demonstrating them. If the croupous pneumonia and the fibrinous bronchitis of the smaller bronchi, by which it is almost always accompanied, be complicated by a catarrhal bronchitis of the larger bronchi, then the purely pneumonic sputum will be mixed with catarrhal elements. Pneumonic sputum is usually very viscid, on account of the nuclein it contains—so much so that the spit-cup may be completely inverted without spilling the contents.

Thin, liquid sputum, especially if it be abundant and dark reddish brown in color, is often an unfavorable sign in pneumonia, as it frequently indicates the beginning of pulmonary edema. Such a dark sputum has been called "prune-juice" sputum, on account of its appearance. However, we should not make a prognosis from the nature of the sputum alone. A thin, liquid sputum is an unfavorable sign only when the other symptoms are very urgent, for not infrequently a liquid sputum indicates the beginning of resolution. Fränkel's pneumococcus can always be demonstrated in the sputum of croupous pneumonia (Fig. 281).

SPUTUM IN BRONCHOPNEUMONIA

We include here deglutition and hypostatic pneumonias. In these disorders the sputum sometimes resembles bronchitic sputum or, like that of croupous pneumonia, it contains blood. This is easily understood, for it is frequently very difficult, aside from the macroscopic distribution, to distinguish broncho- from croupous pneumonia histologically, and, like the latter, bronchopneumonia may also be hemorrhagic, with a more or less fibrinous exudate. The bacteriology of bronchopneumonic sputum may vary considerably. Fränkel's pneumococci are not infrequently found, as well as many other pathogenic micro-organisms.

SPUTUM IN PULMONARY GANGRENE

This is characterized mainly by its intensely disagreeable odor. It is usually very abundant and liquid, and of a dark, dirty-greenish or brown color. Greenish-black particles of necrotic lung tissue can be found macroscopically in it, and besides them, constituents characteristic of hemorrhagic, pneumonic, catarrhal, or purulent sputum. Odorless gangrene is very uncommon. The author once demonstrated an abundance of sarcinæ in the necrotic portions from a case of this sort. If allowed to stand, the sputum of pulmonary gangrene usually separates to form layers, the uppermost layer containing mucus and necrotic portions, admixed with air, which float. The second layer is liquid, and, the third (the sediment) consists of pus-corpuscles and necrotic detritus. Besides the ordinary elements of sputum, abundant bacteria of decomposition, fatty crystals, cholesterin, leucin and tyrosin crystals (Fig. 278, c), pigment, and bits of destroyed lung tissue are seen microscopically. Elastic fibers may be absent.

SPUTUM IN PULMONARY ABSCESS

This is essentially a purulent sputum, and often has a very foul odor. A characteristic of the pus when mixed with water is its fine, shredded, flocculent appearance. (See p. 701.) If catarrh exist at the same time, the pus is mixed with more or less abundant catarrhal sputum, provided the abscess has perforated slowly. If perforation take place suddenly, large quantities of pure pus are expectorated, which contains microscopic elastic fibers and hematoidin, cholesterin, and fatty crystals, besides lung pigment and bacteria (Fig. 278).

SPUTUM IN PERFORATING EMPYEMA

This usually resembles the sputum of a pulmonary abscess very closely. Elastic fibers, if present, occur in very small numbers. Hematoidin and other crystals may be present. (See Fig. 278.) The sputum of an odorless empyema may have a very foul odor after perforation, because the empyema cavity becomes infected with saprophytic bacteria from the lung.

SPUTUM IN PUTRID BRONCHITIS

This is more or less purulent, with a foul odor and abundant bacteria, but without any elastic fibers.

SPUTUM IN BRONCHIECTASIS

The sputum of sacculated bronchiectasis is mucopurulent, but it is often more profuse than is a simple catarrhal sputum, and it is expectorated periodically. Expectoration is easier in certain positions of the body, according to the location of the bronchiectasis. The odor is frequently foul. Its microscopic peculiarities

are quite like those of the sputum of putrid bronchitis. In diffuse bronchiectasis the sputum resembles sometimes the above type, at other times that of simple catarrhal sputum. The odor may or may not be foul.

SEROUS SPUTUM IN PULMONARY EDEMA AND IN PERFORATING SEROUS PLEURISY

The sputum in edema of the lung is colorless or faintly tinged with blood, foamy, and somewhat opaque, and usually profuse. It separates, upon standing, into a lower liquid and an upper foamy layer. The latter is quite abundant. At the bottom there may settle a very thin layer of morphologic constituents, which consist partly of leukocytes and lymphocytes transuded with the edematous fluid, and partly of other elements from some other affection of the lung, present at the same time (bronchitis, pneumonia). Otherwise the sputum of pulmonary edema consists chiefly of pure or slightly bloody serum, which contains a moderate amount of albumin (demonstrated by boiling and addition of acid). The sputum raised after a paracentesis for pleurisy may present all the characteristics of that from a case of pulmonary edema. The French call this expectoration "albumineuse." It is nothing more than the product of an acute edema of the lung following the sudden removal of pressure from the pulmonary vessels. Fortunately, however, paracentesis is not generally followed by any severe symptoms. If a serous pleural exudation perforate the lung and is then expectorated, the sputum will resemble that in edema.¹ This is, of course, very rare, but it does occur. The sputum from a pleurisy can in such cases be differentiated by means of its greater albumin content from the sputum in edema, the fluid, as a rule, becoming solid after addition of acid and boiling.

SPUTUM IN VARIOUS KINDS OF PULMONARY HEMORRHAGE AND IN HEMORRHAGIC INFARCTION OF THE LUNG

In marked hemorrhages of the lung proper, such as occur after injury, or in tuberculosis or new-growths, the sputum may consist chiefly of blood. It is usually bright red, whether it comes from the pulmonary artery or from one of the veins or capillaries, because the dark venous blood of the pulmonary artery in its course along the bronchi has usually been sufficiently aerated to be rendered more or less arterial. The intimate admixture of the blood with air in the lung causes the frothy nature of the expectoration. This frothy appearance and bright-red color, and the fact that the blood is coughed up, are usually characteristic enough to establish the diagnosis that the seat of the hemorrhage is in the lung.

It is, however, sometimes difficult to determine whether the blood comes from the lung or from the digestive tract, especially from the stomach. Differentiation is usually easy, provided the physician himself sees the hemorrhage occur, but it is often very hard to judge from the patient's statements. In the first place, the patient takes no special note of his condition, on account of excitement, and is not sure whether he coughed or vomited the blood; and, in the second place, vomiting may be produced by the violent paroxysms of coughing accompanying a pulmonary hemorrhage; or, on the other hand, vomiting blood from the stomach may start a fit of coughing, on account of the aspiration of blood into the larynx.

When in doubt, reliance must be placed upon the objective examination of the blood. Frothy, bright-red blood favors the diagnosis of a hemorrhage from the lung. Blood from the stomach is more apt to be dark (methemoglobin and hematin), partly coagulated, and not foamy, because it has been more or less digested. Bright-red blood may come from a hemorrhage from the stomach where an ulcer has eroded an artery of the stomach and the blood is vomited in such large quantities that it is still bright red without having undergone any change. On the other hand, in exceptional cases dark blood, without admixture of air, is observed in a hemorrhage from the lung when the eroded vessel is a large branch of the pulmonary artery, from which the dark venous blood has been expectorated so quickly that it has undergone no change.

The reaction is frequently mentioned as a differential point between blood from the lungs and that from the stomach. The former is said to be alkaline; the latter acid, on account of the admixture of gastric juice. But this is true only

¹ Sahli, Ueber, die Perforation seröser Exsudate, etc., Mittheilungen aus klin. u. med. Instituten der Schweiz, 1894, vol. i, part 9.

when the stomach contains a considerable quantity of acid secretion at the time that the blood is vomited.

No one point can be considered absolute in differentiating between a hemorrhage from the lung and one from the stomach. Nevertheless, it is usually not very difficult to decide in any given case. Examination of the patient is more important than is the consistence of the blood, and especially a careful attention to the symptoms preceding or following the hemorrhage. A patient with hemorrhage from the stomach usually gives a history of previous gastric difficulty, or such a disturbance can be determined after the hemorrhage has taken place. Patients who have had a hemorrhage from the stomach usually pass blood in their movements. On the other hand, a patient with hemorrhage from the lung has usually been subject to a cough before or after the bleeding. The expectoration is almost always blood-tinged for days after the hemorrhage, either blood red or brownish. If all these points be taken into consideration, the diagnosis will not, as a rule, be difficult.

Slight hemorrhages from the lung, as contrasted with a true *hemoptysis*, will cause more or less tinging of a catarrhal sputum. The blood is not so intimately mixed with the expectoration as it is in the sputum of pneumonia, but occurs in streaks. A sputum of this sort does not always come from the lung, and so often causes patients quite unnecessary worry. It is very uncommon to have hemoptysis proper from the larynx or trachea (for the simple reason that there are no large vessels there). But slight, streak-like hemorrhages may arise from the small vessels in the mucous membrane of the larger bronchi, the trachea, the larynx, or of the pharynx itself. Bronchitis may sometimes give rise to a hemorrhagic sputum, for, during the last influenza epidemic, some patients expectorated for weeks a blood-tinged catarrhal sputum without any especial disturbance of the general condition. It is not always possible to distinguish between these various conditions. Besides this, it must be mentioned that the clots coming from an epistaxis which has occurred during sleep may become mixed with the sputum in the pharynx as the blood is swallowed. Such sputum may be erroneously attributed to a pulmonary hemorrhage. A careful examination of the anterior and posterior nasal passages will generally settle the diagnosis.

Most cases of hemorrhagic infarction of the lung present a typical sputum; dark and bloody, and resembling pure blood. In its tenacious consistence, however, it resembles the sputum of pneumonia. In fact, the sputum in these cases is an intimate mixture of blood with a tenacious exudation. Besides this typical form, the sputum of infarction shows many varieties, in some cases resembling the sputum of tuberculous hemoptysis, in other cases that of pneumonia.

EXAMINATION OF THE BLOOD

The examination of the blood furnishes a number of important diagnostic data. Several of the methods are so simple that they can be employed at the bedside in daily practice, whereas others are too complicated for such a purpose.

METHOD OF OBTAINING BLOOD FOR EXAMINATION

A few drops are sufficient for microscopic examination, for the determination of the coagulability, for the estimation of the alkalinity of the blood, for counting the cells, for serum reactions, etc. This may be obtained by puncturing the tip of a patient's finger with a needle, or, better, sharp lancet.¹

Francke's instrument² (Fig. 294) pierces the skin very rapidly with

¹The blood is often taken from the lobe of the ear, but this is of no particular advantage.

²See Deut. med. Woch., 1889, No. 2, p. 27. [A similar one is made by Baker & Co., of London. It is smaller and very satisfactory. (See Fig. 295.)—Ed.]

a narrow, needle-like lancet to a depth which can be readily regulated. It does not cause serious pain. Pressing on the lever suddenly releases a spiral spring in the interior of the instrument, which drives the point of the lancet into the skin to a depth regulated by the guard (*d*). The blade may be easily removed and cleansed. The instrument may be adjusted so as to obtain sufficient blood where a larger quantity is needed

(alkalinity). The author formerly strongly recommended this instrument in practice (though at first sight it may seem unnecessary), because it reduces the inconvenience and annoyance of obtaining the blood to a minimum. Unfortunately, it has recently been so badly made that after a short time it refuses service. Very often it is impossible to unscrew the blade, so that it cannot be thoroughly disinfected. The author has, therefore, constructed a simpler, cheaper, and more compact instrument,¹ in which the puncture is also made by a lancet. It is, however, made by manual instead of spring pressure; its depth is regulated by an adjustable guard. Since the depth of the puncture cannot exceed the length of the lancet exposed, the stab may be very quickly made, and is no more disagreeable to the patient than when Francke's needle is employed. Since the blade can be easily taken out, the instrument may be readily disinfected. Dr. J. Ries has also devised a lancet whose blade is a sewing or two-edged needle (easily replaced) which

Fig. 294.—Francke's needle for removing blood for clinical purposes (about one-half its actual size).

may be sterilized in the flame and thrown away after use. A number of extra needles are furnished with the instrument at low cost.²

Before taking the blood it is important to dry the skin carefully, for otherwise the drop spreads out and filling the pipet becomes difficult. Sterilization of the skin is unnecessary.

Fig. 295.—Blood-needle.

If several cubic centimeters of blood be required, wet-cupping may be employed; but since the blood coagulates so rapidly that certain methods of investigation are difficult of execution, it is better to use a cannula inserted into a vein. An ordinary hypodermic syringe with a

¹ Made by Buchi, in Bern.

² This instrument with extra needles may be obtained from M. Schärer & Co., in Bern, for 4 francs.

large needle may be all that is required; but when quite large amounts are necessary, they are best obtained by a larger cannula, through which the blood flows directly from the vein. A piece of tubing is attached to the end of the cannula. The cannula should have a lumen of at least 1 mm. Its length should not exceed 4 cm., otherwise the flow of blood will soon be interrupted by coagulation; moreover, a longer cannula is difficult of manipulation.¹ Whether a needle or a larger cannula is used, it should be very sharp, as the vein may easily be pushed aside by the point. In introducing the cannula the median vein is selected, a fillet is placed about the arm, and the instrument is thrust toward the heart, since this is usually more convenient, and as nearly parallel as possible to the cutaneous surface. The author has convinced himself that this method is not adapted to the quantitative examination of the blood, since the stasis produced by the fillet quickly changes the composition of the blood withdrawn, particularly in respect to the proportion between the solid constituents and the water. This condition of affairs may be avoided, however, by loosening the fillet for one to two minutes before the blood is withdrawn. One does not, however, always succeed in getting large amounts of blood by this method.

QUANTITY OF THE BLOOD; DIAGNOSIS OF HYDREMIC PLETHORA; ESTIMATION OF THE ABSOLUTE AMOUNT OF BLOOD IN MAN

The blood in man is estimated to be about one-thirteenth of the body-weight, but it is very probable that this ratio may be changed under pathologic conditions. There are as yet no positive data, although it would be of the greatest clinical interest to have accurate information upon this point. After acute losses of blood the quantity doubtless remains diminished, perhaps, however, only for a short time. Furthermore, when the body is deprived of water, the liquid portion of the blood is utilized, the blood becomes somewhat thicker, and is diminished in quantity. This probably occurs in cholera and in the acute infantile diarrheas, judging from the great amount of water lost, the slight distention of the vessels, and the increased hemoglobin. Quantitative spectroscopic examinations and hemoglobin estimations have recently shown that the concentration of the blood increases after marked perspiration and after the use of saline cathartics and diuretics, due to the loss of water.

The demonstration of hydremic plethora (*i. e.*, an increased quantity of blood, due to the retention of water) is of particular clinical interest. This demonstration is sometimes possible from a determination of the hemoglobin percentage (see p. 742 et seq.), which falls when the water is retained. It is clear, however, that it is possible to base a diagnosis of hydremic plethora upon the oligochromemic character of the blood only when the latter develops acutely under the observation of the physician, and when hemorrhage or other common causes of anemia can be excluded. With these limitations, the fall of the hemoglobin percentage is a useful indication of hydremic plethora, since hemoglobin cannot quickly enter or leave the vessels, as can the soluble constituents of the blood. It consequently follows that hydremic plethora or retention of water in the blood is frequently to be recognized only by the lowering of the hemoglobin percentage, while the specific gravity, the dry residue, and the osmotic pressure remain normal, since the dissolved constituents, particularly the salts, may remain in the blood. In cases of nephritis, for example, the hydremo-plethoric blood very commonly exhibits even an increased osmotic pressure.

The conditions of so-called "bloodlessness"—the various types of *anemia*—are by no means necessarily due to a deficient quantity of blood, as has been previously supposed, and as is indicated by the name. But the constant sign of anemia

¹ Such cannulæ, which are also used in the Bern Clinic for blood-letting with great advantage, may be obtained from the instrument made by Klöpfe in Bern. They are made in platinum and iridium, as well as in nickeled steel. The former may be sterilized in the flame.

(oligochromemia, pallor of the blood) is due to a diminution in the percentage of blood-pigment. Traumatic anemia, due to loss of blood, is, of course, at the first associated with a diminution in the quantity; but even this condition is rapidly changed to a simple oligochromemia, the blood lost being rapidly replaced by absorption of lymph from the tissues. In pernicious anemia the quantity of blood seems usually to be diminished; in chlorosis, often increased (p. 734).

ESTIMATION OF THE BLOOD-MASS ACCORDING TO KRONECKER AND KOTTMANN

Although, from variations of the hemoglobin content of the blood, it is possible to form some idea of an increase or decrease of the blood-mass, we still lack a clinical method for its exact determination. This is not surprising when we consider that even in animals such estimations are attended with extreme difficulty.

Kottmann¹ has recently described a method that can be applied clinically. This procedure consists of intravenous injections of a known amount of isotonic salt solution. From differences in the content of red blood-corpuscles, before and after the infusion, conclusions as to the amount of blood may be drawn, as, the greater the resulting dilution, the smaller the quantity of blood, and vice versa. Kronecker and Sander in 1881 used a similar method on the dog, but it was soon discarded. These authors counted the blood-corpuscles in a known amount of blood, while Kottmann estimates the corpuscular volume before and after infusion by means of a hematocrit. (See p. 767 et seq.) This instrument was especially constructed for accurate work, and requires a very rapid electric centrifuge with large radius. The infusion is given by means of a needle thrust through the skin directly into one of the veins of the arm. In order to get accurate results, Kottmann advises the use of a salt solution made isotonic with the blood of the person to be examined, according to the method of Hamburger or Dreser. (See Kottmann's original article, *loc. cit.*) For approximate determinations in the sick, in whom the osmotic tension of the blood is assumed to be normal, a 0.9 per cent. sodium chlorid solution is considered isotonic, and is used for the infusion. For the estimation of the corpuscular volume, blood is obtained by a prick from the finger or lobe of the ear. To prevent coagulation, Kottmann adds some hirudin to the blood before centrifuging, and also rubs a few crystals over the wound, so that the blood comes in contact with it at once. Between the infusion and the second estimation five minutes must be allowed to secure a thorough mixing of saline and blood. Three hundred cubic centimeters of sterile salt solution at body temperature are slowly infused, five minutes being consumed by this procedure. By this method Kottmann found that the blood-mass in normal individuals varied from one-twelfth to one-thirteenth of the body-weight. This agrees with the usual assumption. To be sure, this method, as all similar ones, gives only the circulating blood-mass, *i. e.*, the amount of blood which by its active circulation mixes intimately with the salt solution. Naturally, in those vascular areas where the circulation is slow or more or less stagnated, the mixture is incomplete, and the results are, therefore, inaccurate. A drawback to this method and one that may hinder its clinical application is that patients usually experience a rise of temperature after the infusion, although without other abnormal symptoms. This shows that the procedure cannot be considered entirely indifferent. The author advised Dr. Kottmann to experiment, in order to determine whether, by means of a smaller amount of fluid or the use of another salt solution, such as Ringer's fluid or some other similar and more complicated mixture, this method could not be made so indifferent as to commend itself in clinical practice. These experiments have, unfortunately, not yet been attempted. In addition, the ordinary clinical centrifuge must be improved, according to the suggestion of Kottmann, although the employment of the hematocrit could easily be replaced by the method of Kronecker and Sander, namely, counting large numbers of corpuscles. This latter procedure for such purposes is generally considered more accurate.

ESTIMATION OF THE BLOOD-MASS BY HALDANE AND J. LORRAINE SMITH

Haldane and Smith,² following the method of Gréhant and Quinquaud, have determined the human blood-mass by the inhalation of definite non-toxic amounts of carbon monoxid. The principle of the method is as follows: The oxygen capacity

¹ Kottmann, Arch. f. exp. Path. u. Therap., 1906, vol. liv.

² Jour. Physiol., vol. xxv, p. 331.

of the blood of the individual under examination is first determined, this being identical with the capacity of this blood for carbon monoxid. Since the oxygen capacity is proportional to the pigment content, the former is determined by a colorimetric method, in which the blood of the person under experiment is compared, by means of a colorimeter, with ox-blood, the oxygen capacity of which has previously been found by the ferricyanid method.¹ The person to be examined inhales, through a mouth-piece, a measured and harmless quantity of CO (100 to 150 cc.) from a rubber bag, which is supplied with O₂ from a cylinder. The patient also exhales into this bag through a vessel containing soda-lime. CO from a graduated vessel is added to the oxygen in measured quantities of about 30 cc. These amounts of CO are forced into the respiration-bag by allowing water to replace the gas in the graduate. When the required quantity of CO has passed into the bag, the stop-cock of the container is turned off, and the patient breathes from the bag, replenished with oxygen from time to time, until all the CO, as shown by chemical tests, has been exhausted. (See the original for this method.) It is then certain that the measured quantity of CO has been entirely absorbed through the lungs by the blood. The expired carbonic acid is absorbed by the soda-lime. A test is now made of the blood of the patient under experiment, and the CO content is determined by the following method (Haldane described this some time ago). A 1 per cent. solution of the blood from which the previous colorimetric determinations were made is used; 2 cc. of this are put into a calibrated test-tube (a). In a second test-tube (b), of the same caliber, are placed exactly 2 cc. of a 1 per cent. solution of the blood drawn after the CO inhalation. This second tube shows a more intense coloration, on account of the CO present. In a third tube (c) are placed 2 cc. of the first blood after saturating it fully with CO. There are now three tubes, with equal quantities of a 1 per cent. solution of the patient's blood, of which the first contains no CO, the second contains the amount of CO derived from the inhalation, while the third is fully saturated with CO. Add, now, from a buret to tube (a) a solution of carmin of known concentration, the preparation of which will be given below, until its shade corresponds to that of tube (b), and note the amount added—suppose, for example, 0.45 cc. Then continue adding carmin solution to tube (a) until its shade corresponds to that of the fully saturated solution of blood in tube (c), and again note the total quantity added, for instance, 2.5 cc. The following calculations can then be made: Tube (a) contains, after the first addition of 0.45 cc. carmin solution, a total of 2.45 cc., and after the second addition of carmin a total amount of 4.5 cc. The relative quantity of carmin solution first added, as compared with the total quantity added, is in the same proportion to that of the total amount as $\frac{0.45}{2.45} : \frac{2.5}{4.5}$. In order to express this in percentage we make this ratio = $x : 100$. Then $x = 100 \cdot \frac{0.45}{2.45} \cdot \frac{4.5}{2.5} = 33$ per cent. Here x represents the amount of carmin which it was necessary to add, in order to make the shade of the original blood correspond with that of the blood to which CO has been added by inhalation, expressed in percentage of the total amount of carmin, which was needed to make the shade correspond with that of the fully saturated CO blood. Since Haldane has found that these carmin additions are proportional to the corresponding CO content, x expresses the CO content of the blood after the CO inhalation in percentage of the volume necessary for full saturation. After finding these data we calculate the quantity of blood as follows: If, after inhalation of, say, 150 cc., a CO content of 25 per cent. (by volume) of the total amount needed for saturation be found, and if then the amount of CO (or, what comes to the same thing, the amount of O₂) needed for saturation be found with a colorimeter by comparison with ox-blood, of a known O₂ or (CO) capacity, to be 20 in 100 volumes, then the CO content of the blood after CO inhalation equals $\frac{25}{100} \times \frac{20}{100} = \frac{5}{100} = \frac{1}{20}$ by volume. Consequently, we have to multiply the quantity of CO inhaled by 20 in order to obtain the blood-mass, which in this case would be $150 \times 20 = 3000$ cc. These writers believe that the quantity of CO taken up by the muscles and tissues can be disregarded. The carmin solution is prepared in the following way: One gm. of carmin is rubbed in a mortar with several drops of ammonia, and then dissolved in 100 cc. of glycerin. This stock solution is stable. A 1 per cent. watery solution (which is unstable) must be freshly prepared from this each time before using. This dilution is such that 6 cc. of it, added to 5 cc. of a 1 per cent. ox-blood solution, will give the same shade as the blood solution fully saturated with CO. The writers have found, by means of their method, that, contrary to the usual supposition, the amount of blood in man is but $\frac{1}{4}$ of the body-weight. This disagreement with the

¹ See Barcroft & Morawitz, Deut. Arch. f. klin. Med., 1908, vol. xciii, part 3, where the older literature is mentioned.

higher values obtained by Kottmann, using the salt-solution infusion (1: 12 to 1: 13, see p. 732), is so conspicuous that the CO method must be considered as questionable, on account of the loss of CO in the tissues. The author believes that this method is not altogether clinically safe, for, although the amount of CO employed (Plesch states that at least 100 cc. are necessary) probably would not give rise to disturbances of health in a normal individual, yet such might easily be the case with weak, anemic, or dyspneic individuals.

THE CLINICAL RESULTS OF THE ESTIMATION OF THE BLOOD-MASS

The Haldane-Smith method has been used clinically by Plesch,¹ through the application of a new chromophotometer. He has also found the blood-mass to be normally $\frac{1}{10}$ of the body-weight. In cases of chlorosis he found an increase in the blood-mass. Oerum² has also corroborated clinically the experimental evidence of Haldane and Smith. He gives a cut of the apparatus used in this work. He, too, found an increase in the blood-mass in chlorosis. In a case of pernicious anemia, however, he found the blood-mass was normal, while in this disease Kottmann found it decreased (*loc. cit.*). It should be noticed that, in the estimation of the blood-mass, one must consider the weight of the body, since, according to Bollinger, the blood-mass normally is in direct proportion to the muscular development and inversely proportional to the development of fat. The estimations, therefore, are necessarily dependent on the condition of the patient.

THE SPECIFIC GRAVITY OF THE BLOOD

Since large quantities of the blood are now easily obtained, the specific gravity of the blood can be determined with greater accuracy by weighing a given volume, making use of the so-called pyknometer,³ either one already calibrated or a vessel to be calibrated by weighing after it is filled with distilled water. It is obvious that corrections for temperature must be made, in the former case, by bringing the pyknometer, which is filled with blood, to the temperature for which it is calibrated, while in the latter case the vessel, when filled with water, and later when filled with blood, is weighed at the same temperature, generally 15° C. For clinical purposes, however, the specific gravity of the blood can be estimated according to two different methods, using very small quantities of blood. One of these is known as the areometric, the other as the capillary pyknetric, method.

In the *areometric method* (Roy v. Jaksch, Devoto, *et al.*⁴) a drop of blood is placed in fluids of different but known specific gravity, *e. g.*, in different mixtures of water and glycerin. The specific gravity of the blood is the same as that of the mixture in which the drop remains suspended. The influence of coagulation and diffusion militates against this method, and, besides, it is difficult to obtain a great many drops of blood successively from one and the same patient; it has, however, the advantage that it may be performed at the bedside, without any analytic balance.

Hammerschlag's Method.—Hammerschlag⁵ modified this method by placing a mixture of benzol chloroform, of an average specific gravity of 1050 to 1060, in a test-tube or in a urinometer. A drop of blood is then allowed to fall gently into this mixture, and, according to whether the drop floats or sinks, benzol or chloroform is added until the drop is exactly suspended. The drop of blood can then be easily removed by filtering through a piece of linen, and the specific gravity of the mixture determined with the areometer. The fluid may be saved for further use.

Eykmann⁶ has further modified the Hammerschlag method, and thereby has made it more accurate. He has observed that a drop of fluid, although of a different specific gravity, may become suspended in the given chloroform-benzol mixture,

but that the height at which the drop comes to rest is different and constant for each different specific weight of the drop. Eykmann, therefore, employs salt solutions, which show very slight differences in specific gravity (for instance, 0.0002), which can be determined by a fine areometer. The solutions are best prepared by mixing two salt solutions of different concentration. In order to avoid mistaking one solution for another, they are colored with traces of different anilin dyes. A drop of each of these solutions will be suspended at a constant height in the chloroform-benzol mixture. A drop of the blood to be examined is also placed in the chloroform-benzol and then compared with the salt solution. The specific gravity of the drop of salt solution, which is at the same height as the drop of blood, shows accurately the specific gravity of the blood. (For details, see the original work.)

In the *capillary pyknometric method* Schmalz¹ employs a capillary tube (capillary pyknometer), 1½ mm. in internal diameter and 12 cm. long, slightly constricted at the ends so as easily to retain its contents. This tube is dried, filled with distilled water, and then weighed. It is then carefully dried with alcohol and ether, filled with the blood to be examined, and weighed again. If c equal the weight of the empty capillary tube, c' the weight of the capillary tube plus the water, and c'' the weight of the capillary tube plus the blood, then $c' - c$ will be equal to the weight of the water, and $c'' - c$ will be the weight of an equal volume of blood. Therefore the specific weight of the blood will be $\frac{c'' - c}{c' - c}$.

Experiments at the Bern Clinic have proved that this method is easy and accurate if scales weighing to $\frac{1}{10}$ mg. be used.

The results of determining the specific gravity of the blood thus far have shown that it is diminished in all anemic conditions (oligochromemia), and in some other cachectic conditions (nephritis, digestive disturbances), although the percentage of hemoglobin need not be diminished. The normal figures vary between 1.0455 and 1.0665. In men it averages about 1.0550; in women, 1.0535; and in children, 1.0512 (Peiper).

Hammerschlag² advocates a method of estimating the specific gravity of the *blood-plasma*, based upon the above-described areometric principle. The blood is drawn into a capillary tube 3 to 4 cm. long and 1 to 2 mm. in diameter. The tube should be previously washed out with a 3 per cent. solution of sodium oxalate, to prevent coagulation, and then blown out. Both ends of the tube are closed with wax, the tube is set in a vertical position, and the blood is allowed to settle. After the blood-corpuscles have separated from the plasma, the capillary tube is filed in two at the point where the two layers meet, and the plasma is examined according to Hammerschlag's areometric method. The admixture of the sodium oxalate solution causes a slight error in the result, but so slight, according to Hammerschlag, that it need not be considered (?). The specific gravity of blood-serum may be determined in a similar way. The blood is allowed to coagulate in the capillary tube without adding the oxalate, and to stand until the clot has pressed out a sufficient quantity of serum. According to Hammerschlag, the specific gravity of blood-serum varies but very little from that of the plasma. The specific gravity of plasma in a healthy individual ranges from 1029 to 1032. It is diminished in conditions associated with hydrops, especially in nephritis. In these conditions, however, the specific gravity of the plasma may be increased, since in addition to water, proportionately larger quantities of the solid constituents may be retained in the blood.

Eykmann's method, described above, can, of course, also be used in determining the specific gravity of the plasma or serum. In order to obtain plasma it is best to employ a small quantity of hirudin (about 1 mg. to 5 cc. of blood), which serves to prevent the coagulation of the blood without essentially affecting its specific gravity. The gas-content of the blood influences the specific gravity of its fluid portion, depending upon the exchange of ions between the corpuscular and plasma portions of the blood; hence, we must observe the same precautions in these estimations as in the estimation of the reaction of the blood-plasma and blood-serum (see below); that is, the blood must be centrifuged for obtaining serum or plasma with the most careful avoidance of the admission of any air, or it must be shaken with air just as carefully, and in giving results one must state which of these methods was used.

REACTION OF THE BLOOD

The normal reaction of the blood is alkaline, the degree of alkalinity varying under pathologic conditions. The alkalinity of arterial is somewhat greater than that of venous blood. According to Zuntz, it is decreased after coagulation. A decrease in alkalinity is found in severe (pernicious) anemia, but not in chlorosis (Emerson; see, however, p. 738), in fevers, and in acidosis arising from diabetes mellitus or cachexia. According to Cantani, blood may become acid in cholera.

The peculiar color of blood renders titration with indicators very difficult, so that an attempt has recently been made to estimate the degree of alkalinity by determining the amount of carbonic acid contained in the blood, on the ground that this amount depends essentially upon the alkalinity. Theoretically, this deduction is questionable, and; moreover, the method of estimating carbonic acid is too complicated for clinical purposes and requires altogether too much blood.

The blood owes its alkalinity essentially to the presence of sodium carbonate, alkaline sodium phosphate, and the alkaline earths. Löwy and Zuntz¹ divide this alkalinity into two parts, one of which depends upon the diffusible alkaline salts and the other the acid-binding value of protein. Brandenburg² estimates the first portion by bringing the blood into contact with alkalized physiologic salt solutions of varying degrees of alkalinity by means of a diffusible membrane, until the alkalinity of the blood does not change by diffusion. He found that for blood, as a whole, the diffusible alkali is to the total alkali as 1 is to 5; for the serum as 1 is to 2; for the corpuscles, as 1 is to 8. According to Brandenburg, the diffusible alkali of the blood as a whole (alkali tension of the blood measured by means of the alkalinity of a soda solution in contact with which the blood neither gives off nor takes up alkali), is equal to 60 mg. NaOH for every 100 cc. of blood. (Compare this with the normal total alkalinity of laked blood given on p. 738.) The alkali tension of the "whole blood" is reduced in diabetes mellitus (acidosis), in uremia, in pneumonia, and in certain forms of nephritis. Brandenburg's method of estimating the diffusible alkalis is too complicated for clinical purposes. Hamburger has, however, proposed a process by which we can determine the total and the diffusible alkali separately. (See p. 739.) In the technic of obtaining blood for alkali titration one must take into account the fact, proved by Hamburger, that the gas-content of the blood (CO_2 and O_2) markedly influences the division of the ions between the blood-corpuscles and the plasma. If one wish to determine the reaction of the plasma or serum without altering the relations artificially, he must obtain the blood without the admission of any air, and collect plasma and serum respectively in sealed tubes. For this reason Hamburger defibrinates the blood by shaking it, in a flask completely filled by blood, with glass beads. Since large quantities of blood can be obtained from man only by means of a temporary obstruction of a vein, whereby the CO_2 content is artificially changed, the precautionary measures mentioned above are useless for methods which require large amounts of blood and, on the contrary, it is advisable to shake the blood with air, so that it becomes as saturated with O_2 as possible, in order that comparable results may be obtained. For the methods in which small quantities of blood are used the influence of air cannot be eliminated, and here also it seems advisable to give the air the freest access possible. It, therefore, appears that there is no satisfactory method of studying the division of alkali between the corpuscles and plasma as they are found within the body.

The teachings of physical chemistry in medicine have brought forth certain complications with regard to the conception of alkalinity, since very frequently the idea of alkaline reaction is confused with the idea of the hydroxyl ion content. In the latter case, the blood can practically be considered as neutral, for, according to recent experiments, there exists no noticeable excess of the OH^- over H^+ -ions. But there is not on this account any reason for giving up the old idea of the alkaline reaction in favor of the hydroxyl ion theory. Both are equally important properties, but the estimation of the reaction from the action on certain known indicators has the priority, and it would seem to be unwise to replace suddenly an old and satisfactory idea with a new one. This can only lead to misunderstandings. The reader can compare with this the author's similar remarks on the reaction of the urine.

TITRATION OF OPAQUE BLOOD (after Landois-v. Jaksch)¹

This method consists in a modified titration of minute quantities of blood. A series of tartaric acid solutions of known acidity is kept in stock. A measured small quantity of blood—for instance, 0.1 cc.—is added consecutively to 1 cc. of each of these acid solutions. They are stirred quickly, and the reaction is tested with some very sensitive litmus paper. Titration with litmus has, of course, the disadvantage that this dye does not react acid to CO₂. The degree of acidity of the tartaric acid solution which is exactly neutralized by the blood indicates the alkalinity of the blood.

Von Jaksch employs the following 18 test solutions to carry out this method:

Solution	1	contains in	1 cc.	0.9 cc.	$\frac{1}{100}$	} Normal tartaric acid and	0.1	concent. sol. of	Glauber's salt.
"	2	"	"	1 "	0.8 "		0.2	"	"
"	3	"	"	1 "	0.7 "		0.3	"	"
	etc.			etc.			etc.		
"	9	"	"	1 "	0.1 "		0.9	"	"
"	10	"	"	1 "	0.9 "		0.1	"	"
"	11	"	"	1 "	0.8 "		0.2	"	"
	etc.			etc.			etc.		
"	18	"	"	1 "	0.1 "		0.9	"	"

The Glauber's salt solution is added instead of distilled water to preserve the red blood-corpuscles and make the solution permanent.

$\frac{N}{100}$ and $\frac{N}{1000}$ tartaric acid solutions are obtained by diluting a $\frac{N}{10}$ solution which contains 7.5 gm. tartaric acid in 1 liter water.

Von Jaksch obtains the specimen of blood by a wet-cup. Miss Freudberg² undertook to determine the alkalinity of the blood in cases at the Bern Clinic. She employed Francke's needle (p. 729), but used only 0.05 cc. of blood, because it was difficult to get 0.1 cc. from so small a puncture. The blood is sucked into a capillary pipet. Immediately after removal it is blown into a watch-glass containing 0.5 cc. of tartaric acid solution of an average degree of acidity. The mixture in the watch-glass is stirred rapidly with a little glass rod, and the reaction tested with litmus-paper. If acid, the experiment is repeated with a weaker solution until the point is reached when the amount of blood employed neutralizes the acid solution exactly. It is best not to proceed from one solution to the next, but to skip several, so that the outside limits between which the degree of acidity lies may be quickly obtained. Care must be taken to remove the blood as rapidly as possible, as a considerable amount of alkalinity is lost by chemical changes outside of the vascular system. Especial care must also be devoted to preparing a very sensitive litmus paper. (See text-books on Chemistry.³) The method of using litmus paper is as follows: A drop of the mixture of blood and acid is dropped upon the paper with a glass rod, and the fluid immediately removed with a piece of white filter-paper which is known to be neutral. The blood-pigment, which is the disturbing factor, is taken up by the filter-paper, leaving an unmistakable spot on the litmus paper provided neutralization is not complete. Only neutral litmus paper can be used for testing, because the blood-pigment, even after it has been taken up with filter-paper, renders it impossible or very difficult to recognize the reaction upon red acid litmus paper. For this reason neutral (violet) litmus paper should be used. Successively weaker solutions of tartaric acid should be tried until no red spot remains.

It has not yet been definitely determined whether this method of blood-titration with litmus paper gives reliable results. The uncertainty depends upon the well-known peculiarity of litmus pigment to react amphotERICALLY to mixtures of both alkaline phosphates contained in the blood (primary and secondary).

We have already referred to this difficulty under Acidimetric Titration of the Urine. Besides, despite the addition of salt solution to preserve the cells, they gradually become acid in reaction. This happens, to an increased degree, the longer it takes to determine the reaction, and, as a consequence, the results are inexact.

¹ Landois, Eulenburg's Realencyklopädie, 1895, vol. iii, p. 161, second ed.; v. Jaksch, Zeit. f. klin. Med., 1887, vol. xiii, p. 350.

² Freudberg, Einfluss von Sauren und Alkalien auf die Harnacidität, Virch. Arch., 1891.

³ Fresenius, Qualitative Analyse, 1895, sixteenth ed., p. 100, note.

The principal fact obtained by von Jaksch with this method, and corroborated by Miss Freudberg, is that the alkalinity of the blood diminishes in all anemias. (In regard to chlorosis, however, see p. 736.) Von Jaksch found the same to be true for diabetes mellitus, for uremia, and for fever.

The normal alkalinity of the blood determined in this way corresponds, according to von Jaksch, to 0.26 to 0.30 sodium hydroxid, for 100 cc. of blood.

TITRATION OF LAKED BLOOD (after Löwy¹ and Engle)

In order to obviate the difficulty that red cells gradually, and, therefore, to an unknown degree, enter into the reaction through contact of the blood with the tartaric acid, Löwy has proposed to lake the blood before titrating, thereby at once completely admitting the red cells to the reaction. Besides this, he employs lacmoid instead of litmus as an indicator. A flask provided with a long, narrow, partially graduated neck, capable of containing 50 cc., is filled with 45 cc. of 0.25 per cent. solution of oxalate of ammonia and 5 cc. of blood. This solution of oxalate of ammonia lakes the blood, and at the same time prevents coagulation. Titration is performed with a $\frac{N}{25}$ tartaric acid solution (see p. 737) and lacmoid² paper, which has been saturated with a concentrated solution of magnesium sulphate. The 5 cc. of blood may be taken from a vein. (See p. 731.) If so, however, errors due to stasis occur. With fresh human blood Löwy's values varied between 400 and 600 mg. NaOH per 100 cc. of blood. These are higher values than von Jaksch obtained with unlaked blood. H. Strauss's³ values were medium, 300 to 350 mg. per 100 cc. of blood.

S. Engel⁴ modified this method by using a mélangeur (see p. 854), diluting 0.05 of blood 100 times with neutral distilled water. With this mixture in a small beaker he then titrates from a buret, graded into $\frac{1}{10}$ cc., dropping with great care a $\frac{N}{75}$ tartaric acid solution (1 gr. of tartaric acid to 1 liter of water). The end-reaction is tested after the addition of each drop from the buret by wetting a piece of lacmoid⁵ paper with one drop of the solution from a glass rod, and then determining the moment when the yellowish drop (hemoglobin) shows a sharp red line around its margin. Engel's and Löwy's results correspond. The relation of lacmoid pigment to mixtures of primary and secondary alkaline phosphates should be more carefully examined before any judgment is formed as to the reliability of Löwy's or Engel's method. The close correspondence of their values with those of Salkowski (see below) is in favor of their accuracy.

From a practical standpoint, it is interesting to note that Magnus-Levy,⁶ by the use of Löwy's method in diabetic coma, has observed extraordinary marked diminutions of the alkalinity of the blood—diminutions corresponding to 220 to 260 mg. NaOH to 100 cc. of blood. He attributes this diminished alkalinity partly to neutralized carbonates and partly to the combination of the proteins with acids, which consequently lessens the quantity of acid to be neutralized by titration.

SALKOWSKI'S METHOD OF DETERMINING THE ALKALINITY OF THE BLOOD

Salkowski⁷ has recently announced a method of determining the alkalinity of the blood which has the advantage of avoiding direct titration, with all its associated difficulties (color of the blood, uncertainty of the indications in titration in phosphate mixtures). Schlösing's apparatus for determining the amount of ammonia in urine is employed. (See p. 652.) A known quantity of sulphate of ammonia is added to the blood, the alkalinity of which is to be determined, and the amount of ammonia liberated from the alkalis of the blood is then estimated by Schlösing's method. The technic is as follows: Twenty gm. of finely pulverized sulphate of ammonia are placed in the large lower dish of Schlösing's apparatus, and then

dissolved by adding 20 cc. of water. Ten cc. of a $\frac{N}{4}$ solution of sulphuric acid are placed in the upper dish. Ten cc. of blood are then poured into the lower dish with the ammonium sulphate. It is well to add to the blood, at the moment it flows into the graduate in which it is caught, a 1 per cent. solution of sodium oxalate, so as to prevent coagulation. The blood is mixed with the solution of ammonium sulphate, and the globe placed over it as soon as possible.

After five or six days all the ammonia that has been freed has been taken up by the sulphuric acid, and can then be estimated by titration. The entire quantity of sulphuric acid must be used in the titration because, as has been pointed out by Waldvogel, the volume of the acid may change on account of water being given off and combined with the sulphate of ammonia solution.

The technic can be modified by using the Krüger-Reish method for estimating ammonia. (See p. 652.)

Waldvogel gives as normal values for men 350 to 400 mg. NaHO per 100 cc. of blood; for women, 300 to 350. In fever and also in anemia the values were lower. The blood-corpuscles doubtless enter into the reaction in this method. The correspondence of the values found by Waldvogel with those obtained by Löwy would seem to support the value of the method.

Dare's Spectroscopic Method for the Determination of the Alkalinity of the Blood

Dare¹ has recently suggested a method of determining the alkalinity of the blood by titrating laked blood with a $\frac{N}{1000}$ tartaric acid solution. The end-reaction in this method is the disappearance of the characteristic spectrum of hemoglobin and its replacement by that of methemoglobin, the author assuming that the disappearance of the hemoglobin spectrum is coincident with neutralization. Further investigations are necessary, however, to determine the utility of this method, since it has not yet been conclusively shown that the hemoglobin is not destroyed before complete neutralization, and, furthermore, the spectroscopic changes dependent upon variations in the reaction are quite slow in their appearance.

HAMBURGER'S METHOD FOR THE ALKALI TITRATION OF THE BLOOD

With especial reference to the estimation of the diffusible alkalis, Hamburger² first titrates the "whole blood" which has been laked, and then the serum after the method of Löwy with a $\frac{N}{25}$ tartaric acid solution (see p. 737), using lacmoid as an indicator. By this means he determines the total alkalinity of the liquid in question. He then estimates the diffusible alkali in another portion of the same liquid by a method to be described later. By subtraction of the diffusible from the total alkali he determines the non-diffusible alkali. With regard to the influence of the access of air, compare p. 736. The method, which Hamburger employs for the titration of the diffusible alkali, is as follows: One hundred cc. of the blood or serum to be examined are mixed with double that quantity of 96 per cent. alcohol. The precipitate, which contains the non-diffusible alkali in the form of albuminates and analogous substances, is filtered out and washed with alcohol. The original filtrate and washings are collected and placed on a water-bath to drive off the alcohol. Water is then added to make 100 cc., and this is then titrated in the usual way with lacmoid and $\frac{N}{25}$ tartaric acid solution. These examinations show that "whole blood" contains much more alkali than the serum, that the non-diffusible alkali is greater in per cent. by weight in both, and that in both the content of diffusible alkali increases by shaking with CO₂.

ESTIMATION OF THE ION-CONCENTRATION OF THE BLOOD BY FRIEDENTHAL AND SCHULTZ

Friedenthal³ has shown that, aside from the procedures which, on account of their complicated technic, are unsuitable for clinical purposes, the ion-concentration, employing the newer physico-chemical definition of reaction (see p. 736, note 1), can also be more accurately estimated with the aid of indicators. Since the different indicators furnish different dissociation constants, it is possible, according to Frieden-

¹ Proc. Pathol. Soc. of Philadelphia, April, 1903.

² Osmotischer Druck u. Ionenlehre, 1902, vol. i, p. 308.

³ Estimation of the Reaction of a Liquid by Means of Indicators. Zeit. f. Electrochemie, 1904; Fels, *ibid.*, 1904, and Saleski, *ibid.*, 1904.

thal, to find characteristic color changes of certain indicators for the different ion concentrations. For clinical purposes of blood-examination the method of I. H. Schultz¹ is available. This writer prepares, by means of a method which cannot be described here, four acid solutions from hydrochloric acid and sodium acetate, and four basic solutions from barium hydroxid and ammonium chlorid, the ion-concentration of which he computes as follows:

Acid:	1.0 . 10 ⁻⁴	2.0 . 10 ⁻⁵	3.0 . 10 ⁻⁶	2.5 . 10 ⁻⁷
Basic:	0.8 . 10 ⁻⁷	2.0 . 10 ⁻⁸	9.0 . 10 ⁻⁹	7.0 . 10 ⁻¹⁰

The given ion-concentrations are calculated for the H-ion of the acid solution, and for the basic solution the OH-ions are calculated as equivalent H-ions. He also prepares saturated solutions of the following named indicators, by dissolving about 2 gm. of each in 200 cc. of distilled water at 30° C. and then filtering. Schultz now tested the action of these solutions, made up corresponding to their ion-content upon these indicators as follows: Of the indicator solution, 0.1 cc. was used in a small white dish of porcelain with 0.02 cc. of the ion solution, and the reaction observed. From this he worked out the following tables:

ACID.				
HCl : H-ions.				
	1.0 . 10 ⁻⁴	2.0 . 10 ⁻⁵	3.0 . 10 ⁻⁶	2.5 . 10 ⁻⁷

In testing the blood for free H- or OH-ions, about 0.1 cc. of the indicator solution is measured out into a small vessel with a white background, 0.02 cc. of blood is added by means of the capillary hemometer pipet (see p. 744), and, after stirring, the change of color is noted. The specific color of blood will in no way hinder the carrying out of this process, as one can demonstrate by adding a solution of known ion content to the indicator solution. An hydroxyl ion-content of the blood, representing 2.0 . 10⁻⁸ of hydrogen ions, would reveal itself, for instance, through column 6 of the tables, by showing a light tint with phenolphthalein and a yellowish brown with the tropaolin solution. Schultz has found in the insane cases examined by him no

¹ Monats. Psychiatrie und Neurologie, 1908, vol. xxii, Pt. 1.

noticeable changes in coloration of the indicators, which agrees with the opinion of Friedenthal and Höber, so that the blood from a physico-chemical standpoint may be considered as a neutral fluid, i. e., it contains no free H- or OH-ions.

ESTIMATION OF THE COAGULATION TIME AND THE COAGULABILITY OF THE BLOOD

Coagulation Time.—The time elapsing before coagulation of blood occurs varies decidedly under pathologic conditions. It is difficult to give any constant normal figures, because coagulation depends so much upon external conditions, such as temperature, the shape of the vessel in which coagulation takes place, the amount of blood used, and the nature of the wound from which the blood is taken. This is the reason why so little is as yet known regarding pathologic variations.

H. Vierordt¹ recommends a method for determining the coagulation time of human blood which can be performed with very small amounts of blood and which appears to the author to be the most satisfactory for clinical purposes. The technic is as follows: A capillary glass tube, about 5 cm. long and 1 mm. in internal diameter, is filled with blood (by capillarity) for about one-half cm. From the other end there is introduced through the blood a white horsehair (about 10 cm. long), which has previously been carefully boiled with alcohol and ether, care being taken not to touch the end which comes in contact with the blood. To avoid warming, the capillary tube must be handled with Cornet forceps. Once every minute the hair is moved back and forth for $\frac{1}{2}$ cm. through the column of blood. At first no blood sticks to it, but the moment coagulation begins the horsehair will show a reddish discoloration. As soon as coagulation is complete, the horsehair will appear white when pushed further into the tube, or the entire quantity of blood will adhere to it as a compact clot. In order to determine more accurately the length of time necessary for complete coagulation, it has been the author's custom to knot the posterior portion of the horsehair. At the moment of complete coagulation the entire coagulated blood-column may be drawn out of the tube as a compact mass when this knot is brought in contact with its posterior portion. Vierordt found the average time of coagulation with this method to be nine minutes. The author has found, however, that this is subject to extreme variations dependent upon the external temperature and the diameter of the capillary tube, so that the time of coagulation can be assumed to be pathologic only when it is compared with a control test in which normal blood is employed under exactly similar conditions.

A much simpler process for the determination of the coagulation time of the blood is given by Guiart and Gimbert.² Upon each of three slides which have been carefully cleaned in potassium hydroxid solution and then dried in alcohol and ether, is put a fresh drop of blood from the finger. The three slides are placed horizontally under a bell-jar, moistened inside to prevent evaporation, and are tested every minute by carefully tilting the slides and noticing whether the drop changes its form. Full coagulation has taken place at the time when the drop does not change its form with the slide in a vertical position. With this method the coagulation of normal blood generally requires about ten minutes. The blood can also be placed in a test-tube without moistening the slide, and one notes the time in which the drop of blood at the bottom of the tube begins to lose its motility and when the motility is entirely lost.

Wright places a measured quantity of blood in a number of capillary tubes, keeping them at a constant temperature (37°C. and $18\frac{1}{2}^{\circ}\text{C.}$), and estimates the time of coagulation by blowing out the tubes at regular intervals of time. At first he estimated the coagulation time from the absence of motion of the column of blood; now he estimates the coagulation point by blowing out the blood upon blotting-paper and demonstrating the clot.

The method of Russell and Brodie requires a complicated apparatus,³ and depends upon the determination by the microscope of the loss of motility of the red blood-corpuscles caused by the coagulation. The most recent method for the estimation of the coagulation time is that of K. Bürker.⁴ He places a drop of blood and a drop of

⁴ Pflüger's Arch., 1907, vol. cxviii, p. 452, and Verh. d. Cong. f. inn. Med., 1907, p. 515.

distilled water in the cavity of a hollow ground slide and sets it on a water-bath, especially constructed for his purpose, at a temperature of 25° C. This he touches lightly every half minute with a fine glass rod until the first thread of fibrin is caught up. The apparatus can be obtained from Albrecht, the mechanic of the University of Tübingen. The addition of water seems to the author to be questionable.

The time of coagulation is shortened by stasis, after transfusion, after hemorrhage, by hunger, and by the majority of diseases. The statement that the coagulation time of the blood is shortened when it is taken from an area of passive congestion is in marked contradiction to the fact that the blood in the corpse after suffocation is usually liquid. In the intervals between the hemorrhages of hemophilia the author has found the coagulation time to be markedly prolonged. During the hemorrhage, however, this coagulation time may be even shorter than that observed in normal blood. For further details in this connection the reader is referred to the author's article in the *Zeitschrift für klinische Medizin*, 1904-05, "Ueber das Wesen der Hämophilie."

PHYSICAL PROPERTIES AND CONTRACTILITY OF THE CLOT

A few cubic centimeters of blood obtained from a vein (see p. 730) are placed in a test-tube, and the behavior of the clot is observed. If coagulation be abnormally slow, the red corpuscles will be sedimented before coagulation is complete, and the upper layer of the clot then appears as a whitish, so-called "buffy coat." Great differences, which are not as yet quite satisfactorily explained, exist with reference to the rapidity and the completeness with which the clot loosens itself from the wall of the tube and contracts, with a resulting separation of the serum. According to Hayem and LeNoble, one observes a lack of contractility of the clot, independent of the rapidity of the coagulation, existing in grave infectious diseases, *e. g.*, pneumonia, in spite of normal or increased number of blood-plates, which, according to many writers, are responsible for the contractility of the clot, while in other cases (purpura, typhus, pernicious anemia, variola hæmorrhagica, and cachectic conditions of all sorts) the lack of contracting power is associated with a decrease in the number of blood-plates.

DETERMINATION OF THE HEMOGLOBIN IN THE BLOOD

A large number of methods have been recommended for use in this important part of blood diagnosis. The methods available for clinical purposes indicate only the relative amount of hemoglobin contained in the blood examined compared with the normal. Clinically, these relative values, expressed in percentages of the normal, are of primary interest. It is very easy to obtain from them absolute figures if the normal amount of hemoglobin contained in the blood be known. This is in a normal adult 13 to 14 gm. in 100 cc. of blood. As hemoglobin contains about 0.4 per cent. of iron, this would correspond to about 0.05 per cent. of iron content.

By the determination of the relative value of hemoglobin in percentage of the normal it was heretofore thought that the normal hemoglobin content maintained a constant and invariable value, and if this value were placed at a nominal 100, the relative hemoglobin value of any pathologic blood could easily be expressed in percentage of the normal. A blood which had, for example, only $\frac{1}{2}$ of the color value of normal blood would, according to this method of explanation, be considered as containing 80 per cent. of the normal amount of hemoglobin. The author has found by his new hemometer that the hemoglobin content under normal conditions may vary fully 20 per cent. Since this is so, these calculations in percentage of the normal can hardly be employed as formerly. With the exception of the spectrophotometric methods, which are too complicated for clinical use, the author's hemometer for the first time permits accurate and error-free colorimetric examinations. But it is not at all necessary to abandon the very convenient methods based upon these forms of calculation, although it must be borne in mind that the tables which one finds have only an empirical significance, the values of which each observer must establish for himself among his own group of patients, since he decides between which scale values he will limit the normal. (Compare the author's statement regarding his hemometer on p. 751 et seq.)

Leichtenstern found the following values for the hemoglobin content at the various ages, expressed in grams per 100 cc. of blood:

36 hours.....	19.329	3 years.....	10.971
2 days.....	21.160	4 ".....	11.341
3 ".....	20.451	5 ".....	11.151
4 ".....	19.488	6-10 years.....	11.796
8 ".....	17.869	11-15 ".....	11.701
10 ".....	17.129	16-20 ".....	13.034
14 ".....	16.124	21-25 ".....	13.870
3 weeks.....	15.023	26-30 ".....	14.727
4 ".....	15.362	31-35 ".....	15.013
10 ".....	14.293	36-40 ".....	14.685
12 ".....	13.828	41-45 ".....	14.420
14 ".....	14.388	46-50 ".....	12.494
20 ".....	12.928	51-55 ".....	12.696
1-1 year.....	11.373	56-60 ".....	13.150
2 years.....	11.151	Over 60 years.....	14.790

In this table a large number of observations were made on middle-aged and old people, and average figures were taken; but for the earlier periods of life only single observations were made. Nevertheless, the amount of hemoglobin contained in the blood in the first week of life is without doubt one-third larger than the average during the third and fourth decades. During the following weeks the quantity gradually diminishes, and remains one-fourth to one-fifth below the average from the second half of the first year to about puberty. From puberty to the forty-fifth year of life it remains about at the average, and then gradually diminishes. These figures correspond very closely to the variations in the number of blood-corpuscles, except that they are somewhat more striking. (See p. 763.)

The percentages upon clinical hemoglobinometers corresponding to these absolute values can be readily calculated from the above table if 13 to 14 gm. of hemoglobin in 100 cc. of blood be taken as 100 per cent. Stierlin¹ calculated these percentages, and found them to be as follows:

	Corrected percentage. ²
Newborn (1st to 3d day).....	138.88
1-5 years.....	76.58
5-15 ".....	80.50
15-25 ".....	88.88
25-45 ".....	100.00
45-60 ".....	87.50

Miss Perlin, working with Fleischl-Miescher's hemoglobinometer under Stoos's direction, found the following percentages in children of different ages:

Age.	Corrected percentage.	
	Minimum.	Maximum.
2 to 18 months.....	58	78
2 years.....	60	80
3 ".....	69	80
4 ".....	70	84
5 ".....	72	81
6 to 10 years.....	74	85
11 to 14 and 16 years.....	78	88

Hemoglobin determinations are of great value. Only since we have been able to determine the amount of hemoglobin have we recognized that an individual who is very pale need not necessarily be anemic, and that the pallor of the skin of the face may be due to lack of cutaneous transparency or to the fact that the skin contains only a very slight amount of blood. (See p. 38 et seq.) And only since we have been able to limit iron therapy to diseases where there is really a deficient amount of hemoglobin has it become rational therapy.

Clinically, the anemias (see Anemia) include those conditions in which there is deficient percentage of hemoglobin (oligochromemia), as well as hydremic plethora. (See p. 731.) Increased percentages of hemoglobin up to from 110 to 120 per cent.

¹ Blutkörperchenzählungen und Hämoglobinbestimmungen bei Kindern, Arch. f. klin. Med., 1889, vol. xlv.
² In regard to corrected percentage see p. 753 et seq.

are by no means uncommon in so-called full-blooded healthy individuals. (See Polycythemia.)

Numerous observations have established the fact that the hemoglobin percentage increases with increased altitude, just as does the number of blood-corpuscles. (Compare p. 764.)

ESTIMATION OF THE COLOR OF THE BLOOD FROM INSPECTION OF THE BLOOD DROP

One can form a fairly accurate opinion of the presence or absence of oligochromemia by simple inspection of a drop of blood from a finger prick. Pronounced chlorosis and marked pernicious anemia may be recognized by the strikingly pale, watery, and transparent hue of the blood.

TALQVIST'S HEMOGLOBIN SCALE

Talqvist has prepared a chromolithographic scale which corresponds to the shades given by a drop of blood caught on filter-paper according to the hemoglobin content. The gradations of the shades of the scale correspond to hemoglobin values differing from each other by 10 per cent. (normal being set at 100 per cent.). By this method, of course, only marked differences can be determined. It is nevertheless better than no attempt at blood examination.

GOWERS' HEMOGLOBINOMETER

This instrument (Fig. 296) consists of two glass tubes (*a* and *b*) about 11 cm. long and 0.8 cm. in diameter. One of them (*a*) contains 2 cc. of a standard picro-

Fig. 296.—Gowers' hemoglobinometer (about two-thirds the natural size).

carmin solution, the shade of which corresponds as closely as possible to a 1 per cent. solution of normal blood. The other tube, closed at one end, is graduated so that

the level to which 2 cc. of fluid will reach corresponds to 100. If the calibers of the two be exactly alike, this will be exactly the level of the standard fluid in the other tube. Below the 100 mark the tube is subdivided into 100 equal parts, every ten of which are numbered. Each of these parts contain 20 c.mm. Both tubes can be held in a vertical position by setting them into a perforated rubber block (*e*). A capillary pipet (*c*) containing 20 c.mm., with a small rubber tube attached, is used for convenience in sucking up the blood. A non-graduated pipet (*d*) is used for making the appropriate dilution. It contains about 2 cc., and has an opening so small that water which has been sucked into it can only escape drop by drop.

The technic of estimating the amount of hemoglobin is as follows: Twenty c.mm. of blood are sucked up in the capillary pipet as quickly as possible, so as to avoid coagulation. The point of the pipet is wiped off, care being taken not to allow blood to escape from the lumen. Its contents are then quickly blown out into the graduated tube (*b*) partly filled with water. The blood and water are intimately mixed by stirring and by repeated sucking up and blowing out of the fluid. Tube *b* with the blood-mixture and tube *a* with the colored solution are now set up side by side in the rubber block. A thin piece of white tissue-paper is held behind the tubes, and their colors are compared by transmitted light. Water is added from the larger pipet, drop by drop, with repeated stirring, until the color in both tubes is as nearly alike as possible by transmitted light. The line to which the blood solution now reaches indicates at once the concentration of the hemoglobin, as the amount of water added to establish a definite shade of color is naturally proportional to the amount of hemoglobin contained in the quantity of blood used. Gowers acts upon the theory that the blood of a healthy individual has a certain definite and constant hemoglobin content, and the standard solution, therefore, is so prepared that the value 100 would obtain in a very large number of healthy people. But the author has proved that no such constancy of the normal hemoglobin content obtains (see p. 751), so that it is better to regard the scale as purely conventional and not to be deceived by the absolute value found. This instrument is accurate within 5 or 10 per cent., provided that the shade of the standard solution exactly corresponds to the color of blood. The disadvantages of the instrument are, first, that it is quite difficult to make the standard solution so that it will exactly match the color of normal blood, and, secondly, that its color will change after a certain length of time. A special standard solution must be used if the examination be made by artificial light. In view of these disadvantages, the author has constructed a new hemometer, in which some of the principles of Gowers' instrument are retained, and which will meet with the requirements of daily practice. The standard solution, however, is made up with blood-pigment instead of picrocarmin. (See p. 748 et seq.)

FLEISCHL'S HEMOMETER WITH MIESCHER'S IMPROVEMENTS¹

Fig. 297 represents Fleischl's instrument for the clinical determination of hemoglobin with Miescher's improvements. The principle of the instrument is as follows: The stand is like that of a microscope. In the central opening of the objective stage is placed a cylindric chamber, divided into two parts by a vertical partition. This chamber (*M*) has a glass floor. One-half (*a*) is filled with a diluted solution of the blood to be examined. The other half is filled with water. A glass wedge stained magenta slides beneath the chamber by means of the screw T. R. The glass wedge and the chamber are illuminated from below by a plaster-of-Paris reflector P S. The colors in the two halves of the chamber are compared from above by transmitted light. The glass wedge is then adjusted until both sides of the chamber show the same shade, *i. e.*, until the portion of the glass wedge underneath the chamber filled with water has the color of the blood-solution to be examined. The position of the wedge is read off through the window (*m*) in percentage of hemoglobin. Artificial light must be employed—best a candle light. A white light is unsuitable, since by it the color of the wedge does not correspond to that of the blood solution.

The modifications of Fleischl's old apparatus, introduced by Miescher, are as follows: 1. The amount of blood employed can be much more accurately measured with the specially constructed pipet (*mélangeur*) than with Fleischl's former capillary tubes. 2. Blood of varying degrees of concentration can be compared with the aid of this *mélangeur* so that a control is kept of the individual examinations and of the

¹ To be obtained from C. Reichert, Optical Institute, Vienna.

evenness of the coloring of the glass wedge. 3. The scale of each instrument of the improved type is supplied with a caliber table of absolute hemoglobin values (in milligrams), whereas the scale of the old instrument showed the percentage of hemoglobin in relation to a more or less arbitrarily selected average. In this way many of the errors which with the old apparatus were due to the irregular coloring of the glass slide are avoided. 4. The chamber is covered with a glass (D) before attempting to read the percentage, and also with a diaphragm (B), so that the fields examined are sharply defined on all sides without any meniscus. 5. Two chambers of different depths are furnished with the apparatus so that the percentage of hemoglobin can be checked by comparing the two readings. 6. The coloring of the glass wedge has been technically improved, and is much more even than in Fleischl's original instrument.

The mixing pipet above mentioned (*mélangeur*) (Mel, Fig. 297) is made like a blood-counter. It consists of a capillary portion and a chamber 200 times the capacity of the former. The chamber contains a glass bead in the interior. A rubber tube is attached to the *mélangeur*. The drop of blood is obtained in the same way under the same precautions as for counting the blood-corpuscles. (See p. 754.) To dilute 200 times, blood is sucked up into the capillary portion to the mark 1,

Fig. 297.—The new Fleischl-Miescher hemometer.

and then the diluting fluid (1 per cent. sodium carbonate solution), until the chamber is filled. It is then well shaken. To prevent air-bubbles which would render the dilution inaccurate it is well, while sucking up the diluting fluid, to hold the pipet vertically and to roll it gently between the fingers so that the glass bead will free any bubbles adherent to the sides. There are two other marks on the mixing pipet ($\frac{1}{3}$ and $\frac{1}{4}$), one of which corresponds to a dilution of the blood of 1 : 300, and the other of 1 : 400. If the blood cannot be sucked up readily enough to the desired mark, and there is danger of coagulation, the deficiency or excess in the quantity of blood may be determined by the small cross-lines above and below the main marks. Each of these accessory marks corresponds to the $\frac{1}{100}$ of the entire blood-column (up to 1), so that the excess or deficiency of aspirated blood may easily be deducted or added later.

For accurate comparison of the color shades, the solution of blood must be perfectly clear; otherwise the blood always seems somewhat darker than the color of the glass wedge. This is the reason that we employ a solution of soda, which does not quite dissolve the stroma of the blood-corpuscles, but renders it transparent. This soda solution must be reasonably fresh, as otherwise the blood will not appear perfectly clear, on account of the formation of bicarbonate of soda.

The details of technic in using the Fleischl-Miescher instrument for determining hemoglobin are clearly described in the directions accompanying the apparatus. They are copied from an article by Veillon, who demonstrated the reliability of the instrument.¹ Jaquet² claims from numerous experiments that the margin of error in the absolute quantity of hemoglobin determined by this instrument does not exceed 0.15 to 0.22 per cent. by weight of the blood, provided all precautions are taken. This instrument is, therefore, almost as accurate as the spectrophotometer, and is much simpler.

This is very likely true for certain individual Fleischl-Miescher instruments; but they are not uniform, for the color of the glass wedge in one corresponds more closely to the shade of the blood than does that in another. The author could not find a complete agreement with most of them, so that there has always been a great deal of uncertainty in their use. In addition, the coloring of the wedge in each instrument is by no means uniform. The author's assistants have also found that this instrument gives markedly different results with the same blood. Indeed, in view of the varying sensitiveness to color of individual observers, it could scarcely be otherwise, since they are not comparing identical, but merely similar, colors. In this respect the instrument is, therefore, always subject to an error in principle.

GRÜTZNER'S WEDGE HEMOMETER

This instrument, like the Fleischl-Miescher, depends upon the wedge principle. The blood dilution is placed in a narrow wedge-shaped trough, the sharp edge placed vertically below and the wide part, which is open, above. This trough is closed behind with ground glass, and in front with ordinary transparent glass. On looking through at various points of the wedge one naturally sees different shades on account of different thicknesses of the blood solution. The wedge as opposed to the Fleischl-Miescher instrument is stationary. A narrow gelatin plate, colored with picrocarmin, is placed as a standard next to the wedge and parallel with it, with its long axis vertical. In front of the wedge and the gelatin plate is a diaphragm which can be moved in the long axis of the wedge from its base to its apex. The diaphragm has three slits, somewhat more than 1 mm. broad, situated horizontally, parallel with the sharp border of the wedge, and extending over the wedge and the gelatin plate. The diaphragm is moved until one finds on the wedge that thickness at which the blood solution, seen through the middle slit by transmitted light, corresponds with the shade of the adjoining standard plate. The hemoglobin concentration in per cent. of normal can now be read off directly from the scale arranged on the diaphragm. A funnel of black, light-proof paper is used in looking through the slit to prevent interference by daylight. In order to obtain greater accuracy for paler specimens of blood there comes with the instrument a second standard plate which is of such a shade that the 100 point of the scale corresponds to 50 instead of 100 per cent. This instrument seems to have several advantages over the Fleischl-Miescher instrument. In particular, the color of the standard plate corresponds more accurately to the color of the blood than does the glass wedge of the Fleischl-Miescher instrument. The danger of a non-homogeneous coloration of the wedge is also eliminated. Only later observations can show whether or not the picrocarmin of the standard plate is permanent. With reference to the limited value of the percentage scale and the 100 value, see pp. 745 and 751 et seq.

HENOCH'S HEMATOSCOPE

This instrument depends upon the principle that, with a certain intensity of the blood color, or rather with a certain thickness of a slender column of blood, both known, absorption bands of oxyhemoglobin appear of equal width. (See Fig. 233, p. 545.) The apparatus consists essentially of two glass plates, slanting toward each other at an acute angle and thus inclosing a capillary wedge-shaped chamber. The undiluted blood from a finger-prick is allowed to flow into this chamber, thus furnishing a wedge-shaped, capillary blood column. Along the edge of this wedge a scale is attached containing 60 equal spaces, numbered from the base toward the apex of the wedge. The layer of blood is examined with transmitted light directly by means of a small hand spectroscope. (See Fig. 232, p. 544.) The latter is moved in the direction of the long axis of the wedge until both oxyhemoglobin bands are seen to be of equal width. One then observes the scale line which is opposite the slit of the spectroscope, and by its number obtains the absolute value of the hemoglobin content, *i. e.*, grains of hemoglobin in 100 cc. of blood. If one find, as, for instance, in normal blood, that the bands are equal at the line marked 14, which corresponds to a thickness of the wedge of 70μ , one has then determined that the blood contains 14 per cent. by weight of hemoglobin. The test is easy, but the bands are not sharply defined, so that there is an opportunity for certain individual variations.

SAHLI'S NEW HEMOMETER

In the previously described clinical methods for the estimation of hemoglobin, which are those most commonly employed, the solution of blood is compared with an artificially colored substance, *i. e.*, either with a colored wedge of glass or with a solution of picrocarmin. To meet the demands of accurate colorimetry, however, the colored fluid to be examined should not be compared with a different substance, similar in color, but with a solution of known strength of the *same* coloring-matter. This is the only method by which the ability of the human eye to differentiate shades can be completely utilized. In addition to the great difficulty in obtaining an artificial standard color exactly like the color of the blood, whether it be by means of a glass wedge or a picrocarmin solution, the shades of the two colors will not coincide for all dilutions unless the standard color be made with the same substance as that contained in the fluid to be examined. This difficulty is quite apparent in any colorimetric appliance, such as the Fleischl-Miescher hemometer, in which different shades of the standard color must be compared with different concentrations of the blood to be examined. For analogous reasons, an artificial standard color can never be produced the shade of which will coincide with that of the blood both with natural and with artificial light.

The difficulty in applying this colorimetric principle lies in the fact that solutions of hemoglobin are not permanent. It consequently follows that if, in the interest of accuracy, we avoid employing artificial colors, we must utilize some permanent hemoglobin derivative in making the standard solution. The blood-solution to be examined is then converted into a solution of the same derivative, when a comparison may be accurately made. The application of this principle is limited practically by the necessity of employing only those derivatives of hemoglobin which may be produced in solutions of blood by simple chemical reactions.

After numerous attempts the author has succeeded in devising a method by which the hemoglobin of a solution of blood may be transformed into a derivative by quite a simple chemical reaction. With this derivative permanent standard solutions and colorimetric estimations may be made in accordance with accurate colorimetric principles.

The procedure consists simply in diluting the blood with 10 times its volume of $\frac{N}{10}$ hydrochloric acid. After a few seconds the fluid becomes dark brown from the formation of minute particles of hematin hydrochlorate.¹ Although this substance is not held in true solution, it has the same appearance, and when diluted with water forms a clear, brownish-yellow fluid, the pigment percentage of which may be colorimetrically determined by comparison with a permanent standard solution of the same substance.

The color comparison may be made by means of any of the colorimetric appliances, such as Hoppe-Seyler's colorimetric double pipet (see below). In the author's hemometer he has employed the same principle of comparison that is found in Gowers' instrument (see p. 744 et seq.), and which has proved to be so well adapted to the requirements of the practitioner. The standard hydrochloric acid solution, in a concentration corresponding to a 1 per cent. solution of normal blood, is sealed in a graduated glass tube. A similar accurately graduated tube, each division of which corresponds to 20 c.mm., is filled to the mark 10 with $\frac{N}{10}$ hydrochloric acid which has been saturated with chloroform to prevent the development of molds. With a capillary pipet like that employed in Gowers' instrument, 20 c.mm. of blood are introduced into the tube and well shaken. The mixture becomes practically clear and pure brown in color after the lapse of one minute,² water is added until the shade of the mixture exactly corresponds to that of the standard solution, when the hemoglobin percentage may be directly read off, as in Gowers' instrument.

In blood very deficient in hemoglobin, as in severe chlorosis or pernicious anemia, in which color equality is obtained upon the addition of water only to the line 15 or 20, the reading naturally will be relatively inaccurate, for one can scarcely graduate the addition of water under these circumstances, and make a reading with sufficient precision. In such cases three times the amount of blood should be employed, and the test performed as usual, and finally the hemometer reading should be divided by three. In this way, the same accuracy is obtained as with more concentrated blood.

The standard solution is only a suspension and not a true solution, so that a sediment forms after long disuse, and the tube must then be shaken. In the older instrument, this fault was corrected to a great extent by the use of glycerin as a diluent. But sedimentation still took place, and, as the suspension was restored only with the greatest difficulty, water has been used in the newer instrument for making the standard solution. A small glass bead, sealed in the tube, aids in stirring up the sediment. The author has kept the standard solution for a number of years without the slightest change in shade, and so ventures to assert that it is permanent, provided there be no error in its manufacture, such as a lack of asepsis. It once occurred that the stock solution was not well shaken up by the glass-blower, and so the tubes made from the upper portion of the fluid were too light a shade and those from the

¹ The substance produced is not methemoglobin, since the shade differs from that of methemoglobin formed in hemoglobin solutions by the addition of other acids. Its spectrum also differs from that of methemoglobin. The author has recently succeeded in producing Teichmann's hemin crystals from this fluid by extraction with acetic alcohol and subsequent evaporation.

² To obviate mistakes it is essential to wait as long as this.

lower too dark. The faulty tubes were replaced free of cost by the maker. The standard tube must be kept in the dark, for strong light can easily destroy the most stable substance.

The author has further improved this instrument, as compared with Gowers' (see Fig. 298), by placing the two tubes in a perforated black stand of hard rubber, which serves as a colorimetric screen. When the tubes are compared by transmitted light, the rays passing through the sides of the glass blend with the side light, and the colored surfaces are seen beside a black background. The stand is also provided with a ground-glass plate which diffuses the light before it reaches the tubes and obviates all disturbing reflections. By means of these appliances the optical impression obtained is that the fluid is contained in a small compartment with plane parallel sides. Such compartments are really necessary for accurate colorimetric estimations, in

Fig. 298.—Sahlbi's new clinical hemometer.

order to compare completely homogeneous colored surfaces. They are very expensive, however, and not easily obtained in the small size necessary for the minute quantity of blood for examination. The appliance above described renders the employment of plane parallel glass vessels entirely superfluous, as may be demonstrated by the effect upon the eye. In addition to these improvements, the scale of the graduated tube may be turned completely behind the margin of the stand, so that it is not seen until the moment when the percentage is to be read. This has a twofold advantage in that the homogeneity of the colored surface is not disturbed by the scale, and that the investigator, in adding the diluting fluid, is not influenced by a preconceived opinion in reference to the expected percentage. The method may be made still more objective by covering all but the lowermost portion of the tube with black paper, so that the height of the fluid may not be seen at all.

The author has reached the conclusion that by means of these various contrivances, but chiefly on account of the absolute chemical and color congruity of the compared fluids, the simple hemometer devised by him, and made by the optician Büchi in Bern, gives as accurate results as the most exact methods of colorimetric examination of the blood, not excepting the more complicated ones. Furthermore, it is clear that the instrument must give the same result with both artificial and natural light, which is of the greatest advantage to the practitioner, who must work under the most varied conditions. The most accurate result will possibly be obtained in a dark room with artificial light, since under these conditions the eye is the most sensitive to light and color; but even with daylight the results are quite exact. The procedure is practically as simple as with Gowers' instrument.

The author would finally call attention to the fact, which he has directly proved experimentally, and upon this the entire procedure is based, that the brownish-yellow color produced by the addition of hydrochloric acid and subsequent dilution with water is directly proportional to the hemoglobin percentage of the blood examined. In other words, the accuracy of the colorimetric dilution method is not impaired by a dissociation of the hematin hydrochlorid combination which is formed.

REMARKS ON THE STANDARDIZATION OF THE SAHLI HEMOMETER

The author started with the principle employed in the older instruments, all of which, to the present date, are based on the assumption that the blood of a normal person has a constant color intensity, and for this reason the standard solution, as in all other instruments, was so made that normal blood, prepared according to the above-described method, showed, on the addition of water to the 100 mark, the same shade as the standard solution. Normal blood should, therefore, with this instrument give a hemoglobin value of 100 per cent. Experience with the very sensitive and exact new hemometer has, however, convinced the author that such an absolute normal point does not exist, but that in a perfectly healthy individual the normal percentage figures may vary fully 20 per cent. This important fact was not recognized earlier, because with the older colorimetric instruments, made with artificial dyes, the blood solution showed merely great similarity to the standard, but never a perfect color equality. Such physiologic variations of the hemoglobin content of the blood may deprive hemoglobin estimations of some of their value (independent of the determination of the variations in the same individual) if the differences found are not greater than those that may normally appear. Nevertheless, the use of an apparatus which designates the normal as 100 appears problematic, although an average could be obtained from a great number of estimations on healthy individuals, and the standard solution so made that this average corresponded to the 100 point on the hemometer scale. The author has refrained from this procedure in the newer instrument for the following reasons: He has learned by experience that color comparison with saturated color shades is more accurate than with the lighter shades for physiologic optical reasons. Chiefly on this account, in the newer instrument, not the *average* of the very variable normal point, but the *maximum* normal point found, is designated 100. The solution which is, therefore, darker than in the former instrument is so prepared that only his healthiest young assistants actually reach the 100 point.

The majority of individuals show lower values—men, such values as 80, 85, or 90. In other words, the normal point in healthy men varies between 80 and 100 with the newer instrument. Among women the normal values are about 10 points lower, so that one can consider the normal value in women between 70 and 90; and, in fact, the values standing near the lower grade predominate. This change of the instrument will, indeed, seem strange to those who still believe that the hemoglobin content of normal blood is a fixed quantity, but the author believes that it is warranted by facts and that one soon becomes accustomed to it. Were it only necessary to make the shade, which is used for comparison, darker, with the retention of the normal average as 100, this could only have been accomplished by increasing the caliber of the tube. But this would require another instrument, and it is naturally a good policy not to alter an instrument again constructively. On this account, there remained no other alternative than to make the solution more concentrated, so that 100 corresponds to the maximal normal value. The author confined himself to this improvement, requiring no constructive change, even more readily, as thereby that very important and fictitious idea of the constancy of the normal hemoglobin content of human blood would be best opposed. This false idea is responsible for the fact that too many cases of chlorosis are diagnosed, and, at the same time, many very important changes, as incipient pulmonary tuberculosis, are overlooked. With reference to this, see the dissertation of Frl. Dubnikoff,¹ prepared, at the author's suggestion, under the direction of Dr. Seiler, which plainly demonstrates that the hemoglobin values at the lower normal limits (70 in women) show an increase with the administration of iron, at the same time with an improvement of symptoms, and they, therefore, belong to the class which the author has named "masked chlorosis."

Since the hemoglobin value of normal blood varies fully 20 per cent., and since it is influenced by the altitude at which the individual in question lives, and perhaps also by the race, the nutrition, and many other factors, it is necessary that every observer should determine from his practical experience the lowest percentage value which he considers normal, and thereby the value below which he would diagnose an anemia. One must remember, too, the fact that the scale of a clinical hemometer has not, as was formerly thought, an absolute, but merely an empirical, value. For this reason the writers of scientific publications on hemoglobin estimation should be required to state the hemoglobin value which they consider normal for their method of procedure and the instrument used. (Compare Corrected Hemoglobin Percentage, p. 753, etc.)

An observer who possesses a standard tube, which, for some reason or other, does not show a perfect shade, will still be able to undertake accurate estimations with the instrument, for he can correct his tube by means of a number of observations upon a number of healthy individuals, thus finding the limit of the normal value on his instrument, and then easily make the calculation to determine the value which a perfect instrument would give. If, for instance, he find the lowest normal value in a healthy man to be 90 instead of 80, he determines the value which a perfect instrument would give by multiplying the percentage found by $\frac{8}{9}$. In a similar way, one can easily calculate values

¹ Dubnikoff, Clinical Investigation on the Action of Iron and "Marked Chlorosis," I. A. D., 1908.

by correcting the tube used with one that does not agree accurately with it in color. This case arises when an originally faulty or spoiled tube is replaced by a new and accurate one. The hemoglobin content of the blood in question is determined, first with the old and then with the new tube. If, for instance, it be found that the old tube shows 90 and the new tube 80, the old value must be multiplied by $\frac{8}{9}$, in order to correct it for the new instrument, and, on the contrary, with $\frac{9}{8}$ if one wishes to reckon new values on the old instrument.

Since there is a variation in the hemoglobin content of the blood of fully 20 per cent., under normal conditions, it is logical to demand that the percentage calculation of the hemoglobin in the sense of percentage of the normal be abolished. Such means of calculation can be properly employed when there is a fixed normal point. It would be very desirable indeed to gauge the hemometer on the absolute hemoglobin value, *i. e.*, grams of hemoglobin in 100 cc. of blood. The author would have undertaken this change long ago if it were not beset with peculiar difficulties, which depend on the fact that the hemoglobin of various preparations, themselves in a crystalline state, apparently possess different color values on account of the varying water content, so that it is very difficult to state positively that the hemoglobin used for a calibration is perfectly pure; another difficulty is the fact that, since the hemoglobin of the various species of animals varies, one naturally must employ a pure human hemoglobin in order to gauge absolutely the hemometer to be used for estimations on man, and this necessitates large quantities of blood. For these reasons the author has not as yet undertaken any work on these lines, but intends, however, as soon as time permits, to gauge the standard solution spectrophotometrically upon a definite "extinction coefficient" of the corresponding blood solution, so that then, according to the spectrophotometric investigations of Hüfner and others occurring in the literature, we shall be able to calculate absolute hemoglobin values from the hemometer scale readings.

METHOD FOR CORRECTING THE HEMOGLOBIN PER CENT.

If one wish, in spite of the difficulties described, to retain the statement of the hemoglobin value in percentage, he must rereckon the numbers read off directly from the hemometer as percentage of the normal, because such numbers, which one should consider simply hemometer numbers, are indefinite and serve merely to lessen the misunderstanding. The author proposes that the percentage numbers so calculated be designated "corrected percentage." If an observer in a given case find, by means of his hemometer, an amount of hemoglobin equal to 70, while he normally finds by this means an average amount equal to 80, the corrected percentage value of the given blood will be $\frac{70}{80} \cdot 100 = 87$ corrected percentage. If the hemometer in question give an average value in women equal to 70, then a hemometer reading of 70 gives a corrected percentage value of $\frac{70}{70} \cdot 100 = 100$ corrected percentage. As one can see, the corrected percentage value of equal shades for the two sexes comes out differently, and this fact must naturally be remembered in the calculation of the color index (p. 765).

THE HEMATOSPECTROPHOTOMETER

The most accurate method of determining the amount of hemoglobin is by means of the spectrophotometer, first used by Vierordt and perfected by Hüfner.

This instrument, however, is much too complicated and too expensive for practical purposes, so that the author will refer for a description to Hüfner's essay in the third volume of the *Zeitschrift für physiologische Chemie*, p. 562, and to Krüss' work, *Colorimetrie und quantitative Spectralanalyse*, Hamburg und Leipzig, Leop. Voss, 1891.

THE HOPPE-SEYLER COLORIMETRIC DOUBLE PIPET

This very excellent apparatus is also too complicated for clinical purposes.¹

THE COUNTING OF BLOOD-CORPUSCLES

THE COUNTING OF RED BLOOD-CORPUSCLES (*Erythrocytes*)

It is almost impossible to form any idea of the number of red blood-corpuscles contained in the blood by simply inspecting a microscopic preparation, unless the number is so greatly diminished that the preparation shows few or no rouleaux. Actual counting is the only proper procedure. Numerous methods of counting have been advocated. In all of them a known quantity of blood is diluted to a definite proportion with a solution which preserves the red blood-corpuscles, and then those contained in a definitely measured space are counted. The number of red blood-corpuscles in 1 c.mm. of undiluted blood can then easily be calculated by simple multiplication.

The simplest and most practical blood-counting apparatus is that constructed by Thoma and Zeiss (Fig. 299). It is based upon the older principles of Malassez, Hayem, and Gowers. It consists of two parts, a counting-chamber upon a slide, and a mélangeur. The latter consists of a capillary pipet with an ampulla containing a freely movable glass bead. As is shown in the figure, the mélangeur is so constructed that the ampulla contains 100 times the cubic contents of the capillary tube. A rubber tube is attached to the upper end for convenience in sucking up the blood.

The counting-chamber is represented in Fig. 299, *B*, from above and *C*, in section. Two plane glass plates are cemented to a slide. The smaller (*f*) is circular; the larger (*e, e, e, e*) is square, somewhat thicker than *f*, and with a circular opening in the center, in which *f* is centered, leaving between the two a circular moat (*g*). The floor of the moat is formed by the slide itself. The upper surface of *f* is exactly 0.1 mm. below that of *e* (not shown in the cut). In the center of *f*, which forms the floor of the counting-chamber, 1 sq. mm. of the glass is ruled with a microscopic scale into 400 (20×20) squares (Fig. 299, *D*, formed by two series of lines which intersect at right angles). Each square has a surface of $\frac{1}{400}$ sq. mm., each side being $\frac{1}{20}$ mm. Breuer's chamber (see Fig. 301, p. 758), originally devised for counting the leukocytes, may also be used for the red cells. This chamber is covered with a carefully ground cover-glass, made thick enough not to bend. The chamber is therefore, divided into little square prisms, each one of which has a cubic content of $\frac{1}{4000}$ c.mm. This fraction forms the basis of subsequent calculations. The chamber is very carefully ground, and to avoid error the cover-slip should rest very accurately upon the slide. It is carefully pressed down upon the square glass *e, e, e, e*, until the "Newton's rings" which are produced remain permanently (*i. e.*, after the pressure has been removed), merely from the adhesion between the cover-slip and the margin of the chamber. The moat (*g, g*) around the glass (*f*) prevents the blood-mixture upon *f* from running in between the cover-slip and the square glass (*e, e, e, e*), and so altering the depth of the chamber. For the counting of white blood-corpuscles, which, for sake of accuracy, demand a larger surface, the Thoma-Zeiss chamber has been variously modified in its divisions. The most important of these, useful also for the enumeration of the red blood-corpuscles, will be described in the section on the Counting of Leukocytes. (See p. 757 et seq.)

The method of procedure is as follows: In extracting the blood we must avoid any pressure in the vicinity of the puncture, otherwise congestion or lymph exudation may make the results inaccurate. The blood is sucked up into the capillary tube to the mark 1; the ampulla is then filled up to the mark 101 with a 3 per cent.

¹ *Zeit. f. physiol. Chem.*, 1892, vol. xvi, p. 505, and *Lehrb. der physiol.-chem. Analyse*, 1893, p. 414.

solution of sodium chlorid or a 5 per cent. solution of Glauber's salts, or, better still, Hayem's fluid.¹ While sucking up the diluting fluid, the mélangeur should be held vertically and rotated slightly to whirl the glass pearl a little, and dislodge any adherent air-bubbles which would make the degree of dilution inaccurate. A 1 : 100 dilution of the blood is thus prepared for counting. After thorough shaking (the author demands five minutes), 2 or 3 drops of the fluid are first blown out, the point of the pipet is wiped off, and a small drop of the solution is carefully placed upon the center of the counting-chamber, i. e., over the ruled scale. The cover-glass is

immediately adjusted before the corpuscles can sink, and pressed down at the margin until Newton's rings appear. If these do not remain after removal of the pressure, the preparation must be made over again. The chamber and cover-glass must then be still more carefully cleansed, for the trouble is usually due to dust getting between the margin of the chamber and the cover-glass.

¹ Hayem's fluid: Sublimatè, 0.5; sodium sulphatè, 5; sodium chlorid, 2; aquæ destillatæ, 200. This also preserves the red color of the cells, and facilitates a distinction between the red and the white blood-corpuscles.

The mixing pipet frequently causes a great deal of trouble: either the fluid flows out of the capillary part too soon, or, on the contrary, it is drawn into the narrow part of the tube above the ampulla, or even into the rubber tube during aspiration, thus destroying the accuracy of the dilution. Therefore, the author has recently preferred to perform the mixing without the *mélangeur*, as follows: The required amount of the diluent is measured into a small glass by means of a pipet, which must be carefully dried on the outside after the fluid is drawn in. The required amount of blood from a capillary pipet is then added, and the mixture stirred rapidly for at least five minutes with a slender glass rod. In adding the blood to the diluent the capillary pipet must be thoroughly rinsed with the diluting fluid, by drawing it in and blowing it out several times. The pipet used for the diluent must also be rinsed with the mixed solution, in order to clear out any of the diluent that may adhere to its interior. We then place a drop of the solution, by means of a pipet or dry glass rod, on the counting-chamber, and cover it immediately with a cover-glass before the corpuscles sink. This is the mixing apparatus that Hayem has recommended. It is made by Nachet, 17 Rue St. Severin, Paris, but can be prepared by any glass-blower. The pipet for measuring the diluent is graduated for $\frac{1}{4}$ and $\frac{1}{2}$ cc. The two capillary pipets for measuring the blood are graduated as follows: 2, 2 $\frac{1}{2}$, 3, 4, 5 c.mm. for the red corpuscles, and 5, 10, 15, 20, 25 c.mm. for the white blood-corpuscles. The slide is allowed to remain horizontal for about a minute after the cover-slip is in place, until the blood-corpuscles have settled to the bottom of the chamber, and then the corpuscles are counted. For greater accuracy two counting-chambers may be prepared, and compared to be sure that the blood-corpuscles are about evenly

Fig. 300.—Microscopic picture of a part of the ruled surface of the Thoma-Zeiss chamber with blood-corpuscles upon it (high power). The central square bounded by double lines corresponds to the "quadrille" of the Hayem-Nachet chamber (see Fig. 304, p. 762), and has an area of $\frac{1}{16}$ sq. mm.

distributed in each. If this be not the case, fresh preparations should be made after repeatedly shaking the *mélangeur*. A medium power is the best for counting; for instance, a Leitz No. 5 or a Zeiss C or D objective. Fig. 300 shows the appearance of the red cells in a series of squares.

In the modern apparatus each fourth and fifth division line of the chamber is more heavily ruled, and an extra line is ruled halfway between them (Fig. 299, D, and Fig. 300).

For an *approximate count*, each series of 4 squares in a row, which is thus marked off, may be taken as a unit, the procedure being as follows: When the cells in such a series are counted, a memorandum of the number is made, and the average of a large number is multiplied by 100,000 in order to obtain the number per cubic millimeter. Since, if one small square equal $\frac{1}{16} \times \frac{1}{16}$ c.mm., 4 equal $\frac{1}{16} \times \frac{1}{16}$ c.mm., and, since the blood has been diluted 100 times, the factor is 100,000. To avoid counting any cell twice, cells touching the upper and left boundaries of any square are counted in that square; those touching the lower and right sides are excluded.

For *accurate counting* a mechanical stage should be used, and a large number of horizontal rows (20 squares each) counted.

The result is, naturally, more exact the greater the number of squares counted. According to Reinert, the error in counting 200 squares is about 3 per cent. It is therefore, best to count 400 squares, and multiply the result by 1000 to obtain the number per cubic millimeter.

To determine the number of cells contained in 1 c.mm. of blood we divide the number of cells counted by the number of squares; the resulting quotient is

the number of cells in one square; this we multiply by the dilution, and divide by the size of the tiny prism. Suppose, for example, that in counting 100 squares we find 980 cells.

$$\frac{\text{Number of cells, } 980}{\text{Number of squares, } 100} \times 100 \text{ (the dilution)} \times 4000 = 3,820,000$$

The size of each tiny square prism is marked upon the counting-slide, and so need not be memorized.

Unless there is a decided diminution of red cells (anemia), it is easier to count a preparation diluted 200 times. For such a dilution we suck up blood to the first mark 0.5, and then suck the diluting fluid to the 101 mark (just above the bulb). Some examiners find that a sliding stage makes counting easier and more accurate. The more cells we count, the more accurate our result.

If, however, we deal with very marked anemias, with very great decrease of the blood-corpuscles, the usual method of counting will be less accurate than ordinarily, as the absolute number of the counted corpuscles will be less. It is better in such cases to dilute the blood less in preparing the counting mixture. This can be done by using the mixing pipet ordinarily employed for leukocytes. This makes possible a dilution of only 1 in 10 to 1 in 100. (See note 2.) The Nachet apparatus (see p. 756) is also well adapted for counting such weak dilutions.

In the above the fact that the blood contains white as well as red cells has been disregarded. The former should properly not be counted. It is, however, difficult to differentiate them with moderate magnification. Except in cases of leukemia and marked leukocytosis there is no disadvantage in counting all the cells as erythrocytes, since the number of white cells is relatively very small. In cases where the number of leukocytes is too large to be disregarded (*e. g.*, in leukemia and marked leukocytosis) it is best to count all the cells, and then subtract the number of leukocytes determined by methods described below.

In regard to the innovations introduced in Bürker's counting-chamber, see p. 759 et seq.

THE COUNTING OF THE WHITE BLOOD-CORPUSCLES (*Leukocytes*)

It is very difficult to judge the number of leukocytes in a specimen of undiluted blood, because they are usually distributed very irregularly and often seem to be hidden or jammed in between the rouleaux of the red blood-corpuscles. For this reason we dilute the blood, and count them as explained in the following:

Two conditions must be fulfilled: first, the leukocytes must be made easily recognizable with the rather low power used in counting; and, second, considerably larger amounts of blood must be used than in counting red blood-corpuscles, because the number of leukocytes is so small (unless, of course, they are very considerably increased—leukemia). These conditions are best fulfilled by Thoma's¹ method as follows: The blood is diluted with a $\frac{1}{4}$ per cent. aqueous solution of acetic acid. Türk uses a 1 per cent. solution of acetic acid and adds gentian-violet (1 : 6000) to stain the nuclei. The acid dissolves the red blood-corpuscles, leaving leukocytes clearly visible. A special mélangeur is used; its bulb contains only 10 times as much fluid as the capillary tube.² Instead of this the dilution may be

¹ Counting the white blood-corpuscles in the same preparation with the red is not advisable, since the absolute number of leukocytes is too small after the high dilution necessary for red blood-corpuscle counting. If, despite this disadvantage, combined counting be attempted (for merely approximate determinations), the leukocytes must be stained in order to distinguish them from the red cells. This may be done, however, by using, in a 1 : 100 dilution, the following mixture proposed by Toisson: Aq. destil., 160; glycerin neut. (30° B), 30.0; sodium sulphate, 8.0; sodium chlorate, 1.0; methyl-violet 5 B, 25 mg. There is also recommended, as a diluent (1 : 100 dilution), a 3 per cent. NaCl solution with the addition of $\frac{1}{100,000}$ gentian-violet.

² Recently Zeiss has added to his blood-corpuscle counting apparatus a second pipet for leukocytes. In order to use this for the preparation of dilutions from 1 : 10 to 1 : 100, as desired, the capillary portion of the pipet has been marked off into subdivisions. This pipet can also be used for the counting of red blood-cells in cases of marked anemia.

made with Hayem's instruments. These have a great advantage over the *mélangeur* in that, owing to the larger bore of the latter, the fluid very readily runs out. In marked leukemia a dilution of 1 : 100 or even 1 : 200 may be used. After preparing the mixture, the technic is very similar to that for counting red cells (p. 755). It is advantageous, however, to employ a larger counting-chamber, such as those devised by Zappert, Elzholtz, Türk, and B. Breuer. On account of its clearness, Breuer's chamber seems best. Fig. 301 shows how it is divided.¹ The depth of this chamber is 0.1 mm. The middle, finely ruled portion corresponds exactly to the original Thoma-Zeiss chamber (Fig. 299, p. 755) and is used for counting red cells. For counting leukocytes the long rectangles serve as counting units, unless one prefers to count through the entire chamber with a mechanical stage. The total ruled area of Breuer's chamber is 9 sq. mm., that of one long rectangle $\frac{3}{8}$ = $\frac{1}{4}$ sq. mm. The central part, corresponding to Thoma's chamber, is 1 sq. mm.; the little squares (1 mm. square in the figure) actually measure $\frac{1}{20}$ mm. on each side, and have an area of $\frac{1}{400}$ sq. mm. The division of Türk's counting-chamber is also very practical.² With this large chamber a great number of leukocytes may be rapidly counted, and so greater accuracy secured (see below). After the drop of diluted blood has been placed upon the floor of the counting-chamber, it should be examined with a low power, so that the examiner may convince himself that the leukocytes have been evenly distributed. Just as in counting erythrocytes, it is best to employ two

Fig. 301.—Ruling of Breuer's counting chamber. Enlarged 20 diameters, as in Fig. 299. 1 sq. mm. in the figure = $\frac{1}{400}$ sq. mm. The whole figure has an actual area of 9 sq. mm. Each large square = 1 sq. mm.

counting-chambers at the same time, and to be sure that the leukocytes are present in about the same proportions in both chambers.

Türk recommends counting at least 300 to 1000 leukocytes. This is very easy if Elzholtz's, Zappert's, Breuer's, or Türk's chamber be used. If the dilution be 1 : 10, and the leukocytes normal or increased in number, 5 sq. mm. should be counted; in leukopenia, 9 sq. mm. In the latter case the number of cells counted, multiplied by $\frac{1}{10}$, gives the number per cubic millimeter. Reinert found that the probable error was 3.6 per cent. one way or the other, even when 4000 cells were counted. If only approximate counts be wanted, the large rectangles of the Breuer chamber (Fig. 301) can be used as units. We then count the contents of several of these rectangles, and multiply the average (in a 1 : 10 dilution) by 400, in order to find the number of leukocytes in 1 c.mm., or we may use as a unit the medium-sized square, situated in the large central square of the Breuer chamber (Fig. 301), which is included within the double lines, and consists of 16 of the smallest squares. It, therefore, represents an area of $\frac{1}{400}$ = $\frac{1}{25}$ sq. mm. and a capacity of $\frac{1}{25}$ c.mm. In a dilution of 1 : 10 it is, therefore, necessary to multiply the average count by

¹ Made by Zeiss in Jena, described in Berlin. klin. Woch., 1902, No. 141, p. 954.

² Türk, Vorlesungen über klinische Hämatologie, W. Braumüller, Vienna and Leipzig, 1904, p. 95.

2500, in order to obtain the number of leukocytes in 1 c.mm. of blood. This square has the same capacity as the large squares of the Hayem counting-chamber (Fig. 304).

With reference to Bürker's modification of the counting-chamber, see below.

In pathologic cases the count should, if possible, be taken just before a meal, *i. e.*, at a time to avoid the leukocytosis of digestion. The leukocytosis of digestion is almost always absent if very small and frequent meals of fatty and starchy food be taken (Rieder).

The counting of the various kinds of leukocytes (differential count) is best done in stained dry smears. (See p. 794 et seq.) It may be remarked, however, that by the use of certain colored diluents (see Chamber Coloring, by Zollikofer and by Türk, p. 795 et seq.) we may, to a limited extent, make a differential count in the counting-chamber.

In regard to the normal, total, and differential leukocyte count, see pp. 763 and 788 et seq.

BÜRKER'S COUNTING-CHAMBER

While the different counting-chambers, mentioned on p. 757, vary only in the manner of the ruling, K. Bürker¹ has constructed a counting-chamber which varies in principle from the former, since it is filled by allowing the dilution to be counted to flow by capillarity into the chamber, under the edge of the previously applied cover-glass. This method had been previously employed by Alferow,² but it had never received any general recognition. Bürker believes that in this way he obtains a more uniform distribution of the corpuscles in the chamber than is possible with the older

Fig. 302.—Bürker's counting chamber without the positioning clamps.

forms. He has proved to his satisfaction that, with the older methods, even if only a minute interval of time elapse between the placing of the drop of blood dilution and the application of the cover-glass, the corpuscles sink quickly, and, upon applying the cover-glass, an almost corpuscle-free solution will be drawn to the periphery of the counting surface, and the corpuscles will be piled up just where the rulings on the counting surface are found. For this reason, the Bürker chamber is made open at the sides. Bürker sees in this the further advantage that the chamber is totally unaffected by the atmospheric pressure, which he has found can influence the depth of the chamber on account of the air-tight sealing of the chamber. This is not of any importance in the ordinary examination, but is of great importance where there is wide atmospheric pressure variation, as in the examinations conducted in pneumatic chambers, in balloon ascensions, etc.

The Bürker chamber is schematically represented in Fig. 302. *a* and *b* are the two counting surfaces, separated by a transverse groove, and each of them has a lattice-work ruling. This double counting surface allows one to make, without interruption, two successive controlling counts from the same blood dilution. *c* and *d* are the supporting surfaces for the cover-glass. (See the profile view of the apparatus in Fig. 302.) Before putting in the fluid to be counted the cover-glass is so applied that the Newton rings over *c* and *d* are visible. In the newer apparatus there is a contrivance, not shown in the above figure, by which the cover-glass is held down on *c* and *d* by means of two metal clips, fixed into holes in the foundation plate of the

¹ Pflüger's Arch., 1905, vol. cvii, p. 426, and *ibid.*, vol. cxviii, p. 460.

² Arch. de Physiol. norm. et Path., 1884.

chamber. The semicircular projections of *a* and *b* serve for the filling of the chamber, for the blood dilution from the mixing pipet when placed upon them flows by capillarity under the cover-glass. After filling the chamber with the blood dilution one should let it rest on a horizontal plane for at least three minutes, and then determine, by the following method, whether or not the corpuscles are evenly distributed. For the red blood-corpuscles it is better, according to Bürker, to examine the counting-chamber, not with a low magnification, as this gives too small an area, but with the naked eye, after placing the chamber on the stage of the microscope and lighting up its surface from below through the widely open diaphragm. If the distribution be uniform, we observe a general clouding, while an unequal distribution is noted by an unequal clouding. For the white corpuscles, however, one recognizes a uniform distribution by glancing over the counting surface with a low magnification. Fig. 303 shows the Bürker rulings. Bürker counts by means of a movable stage, or, in the absence of this, he moves the counting-chamber on underlying millimeter-ruled paper. Unlike the usual method, he does not count consecutively, but by individual squares, which serve as the unit. These, as shown in the diagram, are separated from one another. Besides this, just as in other forms of counting-chambers, there is a modification in which the counting surface is unruled, and the counting is accomplished by means of three ocular diaphragms of different sizes.

Fig. 303.—Ruling of Bürker's counting-chamber.

By means of a micrometer network, engraved on the base plate at the side of the chamber, these diaphragms are regulated by lengthening or shortening the tube of the microscope, so that they represent areas upon the floor of the chamber of $\frac{1}{16}$, $\frac{1}{25}$, and $\frac{1}{4}$ sq. mm. This modification has the advantage that the blood-corpuscles do not stick in the grooves of the ruling, and the counting can be carried out, as with the Næthel instrument (see below), with less attention and care. The disadvantage is that the diaphragms must always be regulated whenever an objective or ocular is changed. If, however, one always use the same lens, the length of the tube may be adjusted once for all, and the area seen through the diaphragm is, therefore, constant. This method seems to the author to be especially serviceable when only one observer uses the microscope, while at a clinic, where several assistants must use it, the diaphragm apparatus allows too many mistakes. Bürker has found that with his chamber, counting 80 small squares gives just as accurate results as counting 200 squares of the older chambers. This he attributes to a more uniform distribution of the corpuscles. He found, in comparative counting of the red blood-corpuscles, a variation merely of from 0.0 to +0.6 per cent. In using the ruled chamber the squares designated in the figure as "small" serve as counting units for the red blood-corpuscles, while the ones designated "large" are used for the white corpuscles. As a practical rule for calculation, Bürker suggests that, in order to find the number of red blood-corpuscles in millions, in 1 c.mm. of undiluted blood the total number

of corpuscles found in 80 squares of a 1 : 200 blood dilution, be multiplied by 0.01. To determine the white corpuscles in thousands in 1 c.mm. of undiluted blood, one should multiply the total number of white blood-corpuscles found in 100 large squares by 0.025 if a 1 : 10 blood dilution be used. If the counting occupy a long time, or be done at high temperature, Bürker recommends that the preparation be protected against drying by means of a small moist chamber of tin, open on the top, and lined with moist blotting-paper.

THE HAYEM-NACHET HEMATIMETER

This very practical blood-counting apparatus depends upon the same principle as the older chambers, but differs from them in that the chamber of a given depth ($\frac{1}{2}$ mm.) is not ruled, and the cover-glass is not merely laid on, with the formation of Newton's rings, but is held down by the introduction of a drop of water, which spreads out by capillarity and fixes the cover-glass tightly.

In the older instruments, the counting was done by introducing into the ocular a counting-net similar to an ocular micrometer, the surface value of which must be estimated for the lens used and for the given tube length. Leitz also furnishes a similar apparatus. In the newer apparatus the ruling, or rather the counting-net, is projected from a small, transparent photographic positive, with a definite reduction in size, as a real picture on the floor of the chamber. This is accomplished by means of a small projection apparatus placed in the opening of the microscope stage. Both devices have the advantage that one can move the chamber as desired under the picture of the rulings, independently of the divisions, and always have a new part of the blood mixture under the counting-net. The photographic ruling is also superior, in that the deep black lines are more easily visible than the engraved lines of the Zeiss chamber. The network consists of 16 squares, which are arranged to form one large square, and it has vertical and horizontal lines in the small squares to facilitate orientation (Fig. 304). The counting can be best done by regulating the dilution, so that the large square may be used as a counting unit. (See below.) We then simply move the chamber until a sufficient number of such units has been counted. As to the number of squares that must be counted, the accuracy required has to be taken into account, as mentioned on pp. 756 and 758. (For calculation, see below.) By means of this apparatus the counting becomes particularly easy if one employ the counting microscope (microscope hématimétrique).¹ This is a small, inexpensive microscope, to the stage of which is attached a movable stage for the counting-chamber, in addition to the Hayem projection apparatus.

This stage is so constructed that it allows the counting-chamber to move cross-wise exactly the distance of the diameter of a counting unit (a large square). The movement in the anteroposterior direction is accomplished by means of a small lever. We can thus count in the shortest possible time, and without any difficulty, the number of adjacent squares desired or even the entire preparation. The author recommends this counting apparatus on account of its deep black rulings and the simplicity and distinctness of the network, and the counting microscope is recommended on account of its convenient movable stage. The firm of Nachet provides, with this instrument, the convenient mixing apparatus described on p. 756 (mixing tray with ordinary pipet instead of mixing pipets).

When the Hayem-Nachet apparatus with projected counting-net is used, the calculation is done in the following manner: The counting mixture (for red blood-cells) is generally prepared by mixing $\frac{1}{2}$ cc. of the diluent, measured in the large pipet, with 2 c.mm. of blood, measured in the capillary pipet. Since, however, the larger pipet is not entirely emptied, and in the use of $\frac{1}{2}$ cc. of watery solutions 6 c.mm. remain within the pipet, an accurate dilution of 2 : 502 or 1 : 251 is not obtained, but rather a dilution of 2 : 496 or 1 : 248. The area of the larger square of the counting-net, which serves as the counting unit, is $\frac{1}{8}$ sq. mm., so that the cubic content of the counting unit, in a chamber with a depth of $\frac{1}{2}$ mm., is equal to $\frac{1}{16}$ c.mm. We, therefore, have to multiply the average number of the corpuscles per counting unit by $248 \times 125 = 31,000$, in order to obtain the number of red blood-corpuscles in 1 c.mm. of undiluted blood. If one proceed according to the directions on p. 756, i. e., washing out the diluting pipet several times with the blood dilution, the correction for capillary adhesion is not necessary, and the dilution is 2 : 500 or 1 : 250 and the multiplication factor is 31,250. If we wish to have the same grade 757, it is as that obtained by the method with the Zeiss chamber, given on p. of accuracy necessary, in order to use 1000 as the factor, to count 31 large squares and multiply by 1000.

¹ This can be obtained from the optical firm Nachet fils, Rue St. Séverin, Paris.

To count the leukocytes with the Hayem-Nachet apparatus (see p. 756) we mix 25 c.mm. of blood, diluted to the mark 500 on the large pipet ($= 494$ c.mm.) (see above), and then multiply the average leukocyte count for one counting unit (a large square) by 125 (as one counting unit has a capacity of $7\frac{1}{2}$ c.mm.), and then by $\frac{2}{125} = 20.76$, i. e., a total of 2595. If we eliminate, as above described, the error due to capillary

Fig. 304.—Field of the Hayem-Nachet counting microscope. The small squares have an area of $\frac{1}{16}$ sq. mm., the complete large square an area of $7\frac{1}{2}$ sq. mm. The circle is the boundary of the field.

adhesion in the larger pipet, the multiplication factor is 2500. For complete accuracy at least 300 leukocytes should be counted. We, therefore, count through a number of units (large squares), calculate the average, and multiply by the given factor.

CORPUSCLE COUNTING AWAY FROM THE BEDSIDE

The methods for counting red and white corpuscles are such that they must be carried out directly, at the bedside or at least not far away. This is not difficult in hospital practice, but in private practice it is a very different matter, for the carrying of the microscope and all the necessities to the home of the patient is very inconvenient. The very easily transported counting microscope of Nachet is recommended for this purpose (p. 761). Since very few physicians possess this instrument, the author has experimented in order to find out if counting dilutions prepared at the bedside and sealed in glass capillary tubes could not be saved long enough to be taken from the bedside to the laboratory to be counted. He has found that this is possible for a short time only, because the corpuscles gradually clump in the mixture. He recommends that, when the counting cannot be done at the bedside, the undiluted blood be taken (with the addition of a substance to prevent coagulation) and the counting mixture be prepared at home. The best agent for preventing coagulation is hirudin, which also has a protective action on the leukocytes and blood platelets; or, since this is not always at hand, and is rather expensive, ammonium oxalate.

It is sufficient to put a few crystals of one of these substances on the wound, so that the blood comes immediately in contact with it. The blood is run into a capillary tube, and, where possible, the column of blood is placed in the middle and the ends of the tube are sealed off over an alcohol lamp. In order to prepare the counting mixture the ends of the tube are broken off and the blood is allowed to flow into a clean watch-glass. The dilution is then prepared in the ordinary way. Blood so kept (by the use of hirudin) can also be used for preparing smears. Very frequently the morphologic elements are too much changed for this purpose, and it is better to make the dry smear at the bedside, as it is not attended with any special difficulty.

NUMBER OF RED AND WHITE BLOOD-CORPUSCLES UNDER PHYSIOLOGIC CONDITIONS

The number of red blood-cells (Vierordt) in 1 c.mm. of blood is 5,000,000 in men and 4,500,000 in women. In Switzerland the counts show that healthy women have 5,000,000 or over, and men about 6,000,000. These correspond very well with the following figures, which Sørensen published to show the variation in the number of blood-corpuscles at different ages:

TABLE

	Males.			Females.		
	Age.	Number of red cells in 1 c.mm. of blood.	Number of individuals examined.	Age.	Number of red cells in 1 c.mm. of blood.	Number of individuals examined.
Newborn.....	5-8 days	5,769,500 (5,284,500-6,105,000)	3	1-14 days	5,560,800 (5,262,500-5,960,000)	6
Children.....	5 years	4,950,000 (4,750,000-5,145,000)	2	2-10 yrs.	5,120,000 (4,980,000-5,260,000)	2
Adults..... (Students)	19½-22 "	5,606,600 (5,422,000-5,784,000)	7	15-28 "	4,820,000 (4,417,000-5,350,000)	14
Adults..... (Young physicians)	25-30 "	5,340,000 (4,900,000-5,800,000)	6	41-61 " (Nurses)	5,010,000 (4,800,000-5,470,000)	7
Adults.....	50-52 "	5,137,000 (4,910,000-5,359,000)	2			
Adults.....	82 "	4,174,000	1			

In an examination carried out by Frl. A. Perlin, under the direction of Stooss,¹ the normal number of red blood-corpuscles in childhood are given as follows:

Age.	Number of cases examined.	Red blood-corpuscles.	
		Minimum.	Maximum.
2 to 18 months.....	17	4,200,000	5,400,000
2 years.....	13	4,750,000	5,600,000
3 ".....	7	4,800,000	5,350,000
4 ".....	13	4,000,000	5,500,000
5 ".....	16	4,700,000	5,600,000
6 to 9 years.....	7	4,200,000	6,000,000
11 to 14 and 16 years.....	7	4,800,000	6,000,000

From both of these tables, Sørensen's as well as Perlin's, we find that the number of red blood-corpuscles in healthy individuals have at least the same, if not a greater, variation than the hemoglobin content. For this reason, the estimation of the so-called hemoglobin quotient (p. 765 et seq.) and volume quotient (see p. 785 et seq.) is attended with certain inaccuracies.

A number of physiologic conditions have some influence upon the number of red blood-cells. As to the influence of food, authorities differ. According to the observations of Vierordt and Limbeck, there is usually a slight diminution in the number of red cells after eating or drinking, probably to be explained by the dilution of the blood due to absorption of fluid. On the other hand, fasting produces a relative increase. Obese people average a somewhat lower red blood-cell count than thin people (Leichtenstern). Menstruation and pregnancy seem to have no especial influence upon the number of blood-cells. Cathartics and diuretics increase the number of red cells if their action be very marked, possibly on account of the removal of water. A cold bath temporarily increases the number of red cells. This depends merely on the changes in distribution of the cells on account of changes in the

¹ Jahrbuch für Kinderheilkunde, N. F., vol. lviii

circulation. The influence of climates and high altitudes upon the number of red blood-corpuscles is interesting. According to Viault, Miescher, Egger, Jaquet, and others, the number of red blood-cells is considerably increased in altitudes of 1000 to 2000 meters above the level of the sea. This increase occurs within a very short space of time. In Arosa, Egger found that inside of two weeks the number of red blood-corpuscles increased in newcomers from 5,000,000 to 6,000,000. Egger has proved that this increase is due neither to diminution of the plasma, owing to the dry air of the high altitude, nor to a mere difference in the distribution. (See Miescher's works on histochemistry and histology, Leipzig, 1897.) Gottstein claimed that this state of affairs was an illusion, due to the fact that the depth of the counting-chamber was greater with a low than with a high air-pressure; but physics contradicts such an hypothesis. Besides, the hemoglobin percentage increases correspondingly.

In estimating the number of erythrocytes or leukocytes in any given case we must consider that the results are greatly influenced by the condition of the blood-current, the corpuscular elements being increased in the slow capillary current from which counting samples are taken, for, where the blood flows slowly, they are, for physical reasons, more numerous than where it flows swiftly. There is also a normal difference in the number of cells in the blood from different parts of the body; and in stasis the variations in the speed of the current are even greater than when the circulation is normal. The relations mentioned hold good only in stationary conditions, since then the cells are washed away through the finger-prick, because of the decreased resistance and the acceleration of the current following the wounding of the skin. If, on the contrary, the examination be undertaken at a moment when a change of circulation occurs in the pricked area, the results may be just the reverse, since in slowed currents the plasma comes out in advance of the corpuscles, and the less rapid circulation gives a blood richer in plasma and poorer in corpuscles, while the rapid circulation gives a blood richer in cellular elements.

Now, since the blood does not flow at the same rate through all parts of the body, even under physiologic conditions, conclusions as to the total cellular content of the blood, based on the results of counting, can only be drawn with the greatest precautions. Many changes in circulation, induced by hydrotherapeutic measures, the influence of light, etc., which have hitherto been considered without any question as the expression of a general variation of the red or white blood-corpuscle content, are really only the results of local changes in quantity and rapidity of the current of blood in a given part of the body, because of which, as in the punctured finger, sometimes more, sometimes fewer, corpuscles are obtained. These same factors may even give rise to error in interpreting the leukocytosis of infectious diseases, and are also of importance in the viscosity tests of the blood (see p. 850), in so far as the latter are not concerned with isolated plasma, but with the total blood, since the corpuscular content of the blood determines the degree of viscosity.

Rieder (*loc. cit.*) examined fasting people, and found that the ratio of the white to the red blood-cells in healthy adults with a normal red blood-count is 1 : 651, and in children (nine to fifteen years) 1 : 518. Considering the varying number of red cells, these comparative figures are of less value than the absolute number per cubic millimeter. Reider found in fasting adults an average number of 7680, and in children 9660. (See p. 797 with reference to the increased number of leukocytes in the newborn.)

Miss Perlin (*loc. cit.*, see above) gives the following as normal leukocyte counts for children:

Age.	Leukocytes.	
	Minimum.	Maximum.
2 to 18 months.....	8800	15,000
2 years.....	8240	13,400
3 ".....	8900	11,600
4 ".....	8600	13,400
5 ".....	8800	11,200
6 to 10 years.....	7800	9,220
11 to 14 and 16 years.....	7000	8,900

NUMBER OF RED BLOOD-CELLS AND PERCENTAGE OF HEMOGLOBIN IN BLOOD UNDER PATHOLOGIC CONDITIONS; THE HEMOGLOBIN QUOTIENT OF THE RED BLOOD-CELLS

(See also the blood-findings in the individual blood diseases, p. 823 et seq.)

All conditions included under the title "anemia" produce a more or less marked diminution in the number of red blood-cells and in the hemoglobin. Any acute or chronic illness may diminish both the number of blood-cells and the amount of hemoglobin, and so produce an anemia. This is, however, by no means always the case. In acute febrile infectious diseases the red blood-corpuscles and the hemoglobin are as often increased as diminished, the increase being due to the diminution in the amount of blood-plasma, the decrease to the retention of the water and the destruction of the red blood-cells. (See p. 798, *The Blood in Infectious Diseases*.)

Chronic cachexia generally tends to diminish both the amount of hemoglobin and the number of red cells. In the cachexia of cancer the anemia may be very marked and of diagnostic importance. Whenever a marked anemia accompanies cancer, the growth has almost always caused a loss of blood. This loss may be very gradual and not noticed at the time (carcinoma of the stomach and intestines). A gastric cancer, through its profound disturbance of gastric chemistry (achylia) may give rise to pernicious anemia. (See p. 827 et seq.) The blood of tuberculous patients shows at times a diminished quantity of hemoglobin and a smaller number of red blood-corpuscles. This is, however, by no means the rule. Many tuberculous patients with marked pallor and cachexia frequently show a normal blood. Neurasthenic patients rarely show a diminution in the coloring-matter of the blood. Determining the amount of hemoglobin in these cases is of great value with reference to the treatment, as the author has repeatedly emphasized, for a pale appearance is often deceptive. (See section on the Color of the Skin, p. 38 et seq., and p. 823, *Blood-findings in the Individual Anemias*.)

In venous congestion both the hemoglobin and the number of blood-cells are increased. This is a purely mechanical result, due to the slowing of the blood-stream, which leaves the blood-cells in the capillaries. (See p. 763.) This finding does not exclude an increase in the amount of water contained in the blood-plasma, nor hydremic plethora.¹

The Hemoglobin Quotient or Hemoglobin Value of the Red Blood-corpuscles (Color Index).—If the quantity of hemoglobin and the number of blood-cells in any given disease be expressed in percentages of the normal, and the percentage of hemoglobin be divided by the percentage of the number of red cells, a fraction is obtained which, as will readily be seen, indicates how much hemoglobin any one blood-cell contains, as compared with the normal amount. This fraction is called the color index, the blood-corpuscle quotient or value. In order to avoid confusion with the volume quotient described on p. 785 et seq., the author would suggest using "hemoglobin quotient" or "hemoglobin value." Normally this equals 1, but in certain anemias it is sometimes more (pernicious anemia), sometimes less (chlorosis) than 1.

Unfortunately, there exists a good deal of uncertainty in the estimation of the hemoglobin quotient, on account of the fact that the hemoglobin content, as well as the number of red blood-corpuscles, may vary considerably. An exact calculation of the quotient would, naturally, be possible only if there were a fixed normal for

¹ See K. Baranoff, *Beiträge zur Theorie der Flüssigkeitsentziehung und der Behandlung der Circulationsstörungen*, I. A. D., Bern, 1895.

the content of hemoglobin, as well as for the number of red blood-corpuscles. Such a normal must, therefore, be supposed, but then the quotient has but a limited value, as the variations from the normal are not large. There remains no other alternative than to use either the corrected hemoglobin percentage for such estimations (see p. 753), or to use the average of the physiologic extremes as the normal. The hemoglobin content, using the author's hemometer with the new standard solution, is $\frac{80 + 100}{2} = 90$ for men, and $\frac{70 + 90}{2} = 80$ for women.

The number of red blood-corpuscles in an adult, according to Sørensen (p. 763), is 5,000,000. We then have to express the values found as fractions of these normal points in order to find the quotient. If, by the author's new hemometer one obtain a reading of 70 with 4,000,000 red blood-corpuscles, the calculation of the quotient should be done as follows, considering 5,000,000 as the normal number of red corpuscles.

The hemoglobin quotient:

$$Q = \frac{\frac{70}{4000000}}{\frac{90}{5000000}} = \frac{70}{36} = \text{about } 1.$$

ESTIMATION OF THE CORPUSCULAR VOLUME; SEDIMENTATION OF THE BLOOD, AND HEMATOCRIT EXAMINATIONS

The relation of the corpuscular volume to the total volume of the blood in a given unit was previously estimated by allowing the blood to sediment in a graduated glass tube after the addition of a substance retarding coagulation, such as sodium or ammonium oxalate or hirudin. The height of the layer of corpuscles in proportion to the height of the total quantity of blood was then read off. This method, however, has not been adopted, for in human blood, as opposed to horse's blood, where this method is very useful, the corpuscles settle so slowly that, in the interval, chemical changes occur which materially influence the result. Hedin¹ recommended that sedimentation be hastened by centrifuging, and in order to use the smallest quantity of blood possible, he employed the so-called hematocrit, a graduated thermometer tube open at both ends and closed during the act of centrifuging by means of rubber caps. This method has been adopted and modified by Eykmann,² Hamburger,³ Gärtner,⁴ and Köppe.⁵ The centrifuging must naturally be continued until the column of cells remains a constant height.

Originally, the blood for the hematocrit examination was mixed with special chemicals to hinder coagulation, such as Müller's fluid or ammonium oxalate. Since, however, these solutions are neither chemically nor physically inactive, and since, if they be not made isotonic with the blood, they artificially change the corpuscular volume, control experiments must be done in each case in order to prepare a solution that is isotonic with the blood. When oxalates are employed, a precipitate of calcium oxalate is deposited with the corpuscles and so alters the volume. For these reasons it is properly recommended by more recent writers that such substances delaying coagulation be not used, and that coagulation be hindered by various other means.

Köppe (*loc. cit.*) coated the inner surface of the hematocrit tube with a thin layer of cedar oil, which, as is well known, retards coagulation. Just enough of this is drawn up in the tube to moisten the entire inner surface. The blood to be tested is placed immediately in the capillary tube, which is then sealed and centrifuged. The reading of the height of the column of blood before centrifuging will give erroneous results, since noticeable quantities of oil would then be reckoned as blood. After the centrifuging the oil, by virtue of its lightness, appears on top of the column of blood, so that a reading taken at this time will give accurately the height of the column of blood (or, rather, corpuscles and plasma reckoned together), sharply marked off from the oil, and also the height of the corpuscular layer. Since the slightest impurity of the oil or irregularity of the wall of the tube may produce coagulation, Köppe recommends that several tubes be centrifuged together or consecutively, and that sharply defined columns and harmonious results from the various tubes should be demanded.

⁵ Arch. f. (Anat. und) Physiol., 1895.

Hamburger, in order to prevent interference by coagulation, used defibrinated blood. He prepares a small glass tube, with a capacity of about 0.5 to 1 cc., sealed at one end, corked at the other. He places a few glass beads in the tube, fills it with the blood to be examined, closes the tube, and shakes for fifteen minutes in order to defibrinate. The blood is then filtered through a very small filter, in order to free it of the particles of fibrin, and 0.06 cc. of the filtrate is then measured by means of a capillary pipet, placed in one of the hematocrit tubes to be described later, and centrifuged until a constant corpuscular volume is obtained. After shaking the blood with glass beads the serum is stained somewhat red, but, according to Hamburger, this does not give rise to any error in the reading of the corpuscular column, because only a very few corpuscles contribute to this staining. Hamburger employs, instead of the ordinary hematocrit tubes, which are open at both ends and have to be closed by a special device, a graduated tube of the form and size shown in Fig. 305, sealed at one end and funnel shaped at the other. These same tubes are used for determining the osmotic pressure described on p. 768.¹ The blood should be made to flow slowly from the pipet into the funnel-shaped end of the tube. No noticeable amount of blood is left in the pipet. Hamburger oils the point of the pipet to prevent the last drop of blood from adhering to it. The author recommends the Hamburger tube, as he has had some very unpleasant experiences with the original hematocrit tubes, because they leak very readily. The tube is easily cleaned by filling the funnel-shaped part with water, and dislodging the sediment which lies in the capillary portion of the tube with a thin strip of whalebone. The mixture is shaken up and poured out several times until the tube is apparently clean; the remainder of the organic substances is totally removed by rinsing with a mixture of sulphuric acid and potassium dichromate. It is again rinsed thoroughly with distilled water and dried with alcohol and ether.

Kottmann prevents coagulation by the addition of dry hirudin. In his method of estimating the blood-mass (see p. 732) he allows the blood to flow directly from a vein into a glass containing a weighed or an estimated amount of hirudin. If we wish to carry out this method on the capillary blood obtained from the finger in the ordinary way, the hirudin powder is dusted on the finger immediately after making the puncture, so that the blood mixes with it as soon as it appears on the surface. Since hirudin is very soluble, practically hygroscopic, a sufficient mixing is spontaneously and immediately obtained. The mixing can be made more complete later on by drawing the blood in and out of the capillary pipet. The action of good (fresh) hirudin in preventing coagulation is so marked (1 mg. prevents the coagulation of 5 cc. of blood) that a hardly measurable quantity is necessary for hematocritic experimentation. The volume of blood, therefore, and its osmotic concentration, is not influenced to any noticeable extent by the hirudin added.

Finally, Capps² employs the hematocrit for estimating the volume quotient of the blood (see p. 785) by centrifuging the blood without adding anything, and disposes of coagulation by using a very powerful and rapid electric centrifuge, which sediments the corpuscles completely before coagulation begins. This procedure meets with difficulties in case the coagulability of the blood be very markedly increased.

The objection that a change in the volume of the blood-corpuscles is induced by the addition of non-isotonic solutions must now be discredited, on account of improved technic, but there is still the objection that a certain amount of fluid remains mixed with the corpuscles and is measured along with the corpuscular volume.

Fig. 305.—Hamburger's hematocrit tube. Actual size.

¹ In this connection see p. 769, note 2.

² Amer. Jour. Med. Research, 1903, vol. x, No. 3.

Eykmann has found (Pflüger's Arch., 1895, vol. lx, p. 340) that this error may be eliminated by using a rapid centrifuge (2600 revolutions a minute) for one and one-half hours. The corpuscular volume found must then be multiplied by 0.9025. Centrifuging for so long a time is, however, hardly necessary for practical purposes, and it has been ascertained that useful relative values are obtained by centrifuging for such a time that there is no noticeable change in the corpuscular volume reading after centrifuging an additional two minutes. To obtain this result quickly the weight of the centrifuged mass must be as light as possible. This is obtained by procuring with the centrifuge some lightly made hematocrit arms, which may be easily inserted in place of the ordinary heavy ones. These should be so delicately made that they offer but slight resistance to the air. In using the Hamburger tubes it is necessary, for mechanical reasons, to fasten the tube directly in the ring by a cork. In the ordinary clinical centrifuge these rings support the aluminum cups which hold the glass centrifuging tubes. When these cups are removed, the weight of the moving mass and the atmospheric resistance is so markedly reduced that, even without special hematocrit arms, a decided increase in the number of revolutions is obtained.

The author believes that if the improved technic be employed, and the precautions above described be carefully regarded, the hematocrit examination should again be made use of clinically. It was mainly discredited on account of faulty methods, and also by the fact that observers expected to see, contrary to fact, a definite relation between the number of corpuscles and their volume. This is naturally impossible on account of the very unequal size of pathologic corpuscles. In spite of this we should observe that a comparison of the counting results with the findings by the hematocrit examination gives valuable information, because it allows an estimation of the so-called volume quotient, *i. e.*, the average volume of an individual corpuscle, and also because the percentage volume of the corpuscles in the blood may be of clinical interest, particularly in following up the changes of the osmotic condition of the blood at short intervals of time. For criticism on the hematocrit methods the reader is referred to Hedin, Eykmann, and Köppe (*loc. cit.*). The red blood-corpuscles in normal cases form about one-half the volume of the blood. Ordinarily, this corpuscular volume is expressed as percentage of the blood-mass, so that the normal red corpuscle volume is about 50 per cent. The method of calculation with the Hamburger tube is shown in Fig. 305.

In centrifuging out the corpuscles a thin, whitish layer may be recognized on top of the layer of red cells. This is composed of white corpuscles, and at times a similar layer of a somewhat different shade, due to blood-plates. Marked grades of leukocytosis, as in leukemias, may be recognized in this way without further examination.

POWER OF RESISTANCE OF THE ERYTHROCYTES TO HYPOSMOTIC AND OTHER INJURY

It is well known that when a small amount of blood is placed in an excessive quantity of a hypotonic saline solution, the blood-pigment passes out of the erythrocytes, so that a so-called laked blood results. In such experiments the stromata of the erythrocytes are not dissolved. In saline solutions which are isotonic or hypertonic to the blood-plasma, the blood-pigment does not pass out, at least not within a limited period of time. For this reason it was formerly believed that the osmotic pressure of the blood-plasma could be determined by finding the concentration of the saline solution which would preserve the erythrocytes intact. It has nevertheless been shown that the escape of the hemoglobin from the erythrocytes under these conditions is by no means a purely osmotic phenomenon, but that it is also dependent upon the specific sensibility of the stroma of the erythrocyte, which holds the hemoglobin within the corpuscle. This has been absolutely proved by the observation that all of the erythrocytes of an individual are not equally sensitive to the same hypotonic solution. In a slightly hypotonic saline solution the osmotic concentration of which closely approximates that of the blood, a number of erythrocytes are destroyed by the escape of their hemoglobin, while others do not lose their pigment until the saline solution is much more markedly diluted. This could not be the case were the phenomenon purely osmotic in character. For this reason we are no longer justified in assuming that the osmotic concentration of the blood-plasma may be indirectly obtained by determining the resistance of the erythrocytes to saline solutions of varying concentration. This false idea is also responsible for the incorrect supposition that a saline solution of 0.7 or even 0.6 per cent. is physiologic, *i. e.*, isotonic with the blood-plasma, when, as a matter of fact, the direct determina-

tion of the osmotic pressure of the blood by means of cryoscopy (see p. 845) has shown that a 0.9 per cent. saline solution is isotonic with human blood.

Hamburger¹ proposed a method for estimating the resistance of the red corpuscles to hypotonic salt solutions, using for these determinations a large number of funnel-shaped tubes.² (See p. 767.)

The tubes are prepared with 2 cc. of saline solution of different strengths, each one varying from the next by about 0.01 per cent. To each tube 0.05 cc. of blood is added, by means of a capillary pipet, and the mixture is stirred up with a strip of whalebone. This latter procedure also removes the air from the capillary part of the tube. After standing for fifteen minutes the tubes are centrifuged, and one then notes by contrasting the fluids that have become clear, the concentration in which there is the faintest trace of hemoglobin stain in the salt solution, and the concentration in which the maximum hemolysis, *i. e.*, the complete surrendering of the coloring-matter, is reached. The solution with which we obtain the minimum hemolysis shows the minimum resistance, while that giving total hemolysis represents the maximum resistance, and the solutions between these extremes represent the range of the resistance. The fact that the surrendering of the coloring-matter by the corpuscles is not always complete in a given dilution is explained, according to Hamburger, by the supposition that individual corpuscles have different resistances. Hamburger emphasizes the fact that the results of the examination of the blood for resistance to varying osmotic pressures are hardly comparable unless carried out with the technic proposed by him and with the employment of his tubes. On account of the influence of the oxygen, or rather carbonic-acid content of the blood, on the resistance of red blood-corpuscles as shown by Hamburger, it is recommended that the blood be spread out on the funnel-shaped portion of the tube in contact with the air for several seconds before mixing it with the salt solution, so that the corpuscles may first take up the oxygen of the air.

According to Hamburger's investigations, the resistance of the red blood-corpuscles to osmotic destruction is a very complex phenomenon, from which no definite clinical conclusions can as yet be drawn, since we do not know the determining factor in any given case. Hamburger states rightly that a decreased resisting power found by his method in no way shows, of itself, a diminished resistance of the stroma of the corpuscles against osmotic swelling, since, according to his theory of the structure of the stroma (reticular structure), besides the resistance of the network, the swelling capacity of the blood-corpuscle content, or its osmotic pressure, as well as the percentage volume of the swollen content in proportion to the stroma, are additional factors. Unfortunately, it is not decided which factors determine the result, as only one, namely, the swelling power which corresponds to the osmotic pressure of the blood, can be directly estimated.

P. Ribierre's³ method is similar to the above. This writer uses a 0.5 per cent. salt solution, and places in a very small test-tube 50 drops; in a second, 48; in a third, 46 drops, etc., and then adds distilled water sufficient to make 50 drops in each tube. A definite amount of blood (20 c.mm.) is put into each tube from the capillary measuring pipet (p. 744). Normally, the hemolysis begins in a tube containing 44 drops of salt solution and 6 drops of distilled water, and is complete in the fifth or sixth following tube. The results are described as "slight," "distinct," "very distinct," and "complete," and one states in which of the dilutions these grades of hemolysis are found. French writers previously represented the results of these determinations in the form of a curve, the abscissa of which represented the number of drops of salt solution used, and the ordinates represented the four grades of hemolysis.

One can then easily calculate at what percentage concentration the hemolysis begins. If, for instance, the tube containing 44 drops express the extreme concentration, the percentage will be $\frac{44}{50} \cdot 0.5$ per cent. = 0.44 per cent.

With a sensitive blood, Ribierre begins with stronger saline solutions, *e. g.*, 0.7 per cent., and puts in the first tube 70 drops; in the second, 68; then, 66, 64, etc., and adds distilled water up to 70 drops in each case. If hemolysis begin in the tube containing 64 drops, the saline concentration is $\frac{64}{70} \cdot 0.7$ per cent. = 0.64 per cent.

According to Hamburger,⁴ marked decrease in the resistance of the red blood-

⁴ Osmotischer Druck- und Ionenlehre, Wiesbaden, 1902, p. 365.

corpuscles to injury by hyposmotic solutions has been found in fever, chlorosis, pernicious anemia, and cyanosis. Strong resistance of the red cells to hyposmotic solutions has been found in carcinoma and jaundice. Clinically important results have been found in jaundice by Chauffard,¹ who found, by Ribierre's method, that obstructive jaundice can be differentiated from other types, designated by the writer as "hemolytic" (terms which correspond with "hematogenous" or "hematohepatogenous" jaundice, see p. 44 et seq.), by the fact that in obstructive jaundice the resistance of the red blood-cells to hyposmotic destruction is raised, while in hemolytic jaundice, on the contrary, it is lowered. We may, therefore, using Ribierre's method, find in obstructive jaundice hemolysis beginning in a concentration of 0.36 to 0.38 per cent., i. e., in a tube made up of 36 or 38 drops of a 0.5 per cent. salt solution, with the addition of 12 and 14 drops of distilled water. In hemolytic jaundice, on the other hand, hemolysis begins at 0.4 per cent. Chauffard found a lessened resistance especially in pernicious anemia with jaundice, and in the so-called "hereditary jaundice" of Minkowski. This agrees exactly with Minkowski's explanation, which is that this is a hematogenous, or rather hematohepatogenous, jaundice, due to destruction of red blood-cells which appears in the disease which accompanies splenomegaly, as a result of splenic changes.

The determination of the power of resistance of the erythrocytes to hyposmotic injury is not sufficient to settle all the questions in reference to their resisting power, since Chvostek² (in contrast to Murri), found that in paroxysmal hemoglobinuria the power of resistance of the erythrocytes to saline solutions is normal, while they show but slight resistance to mechanical injury (shaking) and to stasis within the body.

The peculiar behavior of red blood-cells in this disease under the influence of cold is mentioned on p. 44.

The testing of the resistance of red blood-corpuscles to specific hemolytic action, for example, the saponins, is worthy of clinical investigation.

OTHER MORPHOLOGIC RELATIONS OF THE BLOOD

TECHNIC OF THE MICROSCOPIC EXAMINATION OF THE BLOOD

For this purpose either fresh or stained dried preparations may be employed.

MICROSCOPIC EXAMINATION OF FRESH BLOOD

The most important alterations in the blood which are peculiar to diseases of the blood proper may be recognized in fresh specimens. Certain precautions should be taken in preparing the latter. Too much pressure applied near the puncture to increase the flow may deform the red blood-corpuscles. If, however, the blood will not flow without it, light pressure may be applied at a little distance from the puncture. A scrupulously clean cover-slip should be very gently touched to the drop of blood, so that only a very tiny amount of blood adheres. Too large a drop makes too thick a preparation and too pronounced a rouleaux formation, so that the finer details cannot be detected. The cover-slip is immediately dropped very carefully upon a clean slide. Delay will allow drying and consequent deformity of the cells. Pressure on, pulling, or sliding the cover-slip should be avoided. Unless these precautions are observed, a most beautiful microcytosis or poikilocytosis (see below) may be artificially produced. The blood should be distributed under the cover-slip in a uniformly thin layer, but this effect must be produced entirely by capillary action. The preparation should be examined immediately, because the blood-corpuscles soon begin to shrink from loss of water, and to assume all

¹ Semaine Med., 1907, No. 3.

² Ueber das Wesen der paroxysmalen Hämoglobinurie, Wien, F. Deuticke, 1894.

sorts of bizarre shapes. Such a preparation can be preserved for a limited time if evaporation be prevented by smearing the edge of the cover-slip with oil. Diluting fluids should be avoided.

The variation in size and shape of the red blood-corpuscles (poikilocytosis (see p. 782 et seq. and p. 785 et seq) can easily be recognized in unstained preparations if the smear be sufficiently thin. The color variations (variations of hemoglobin content, anisochromia) of the red blood-corpuscles can also be seen. This generally goes hand in hand with the variations in size and shape, and, like these, is seen best in severe pernicious anemia. (See pp. 783 and 826.) The basophilic granules of the red cells (see p. 784) can occasionally be recognized in a fresh smear as colorless spots. An experienced observer can recognize also the nucleated red cells (see p. 784 et seq.) in fresh smears, and may even be able to differentiate normoblasts from megaloblasts by the size of the nucleus and the rim of protoplasm. The red-cell nucleus appears in these fresh smears as a sharply defined, colorless area inside of the red blood-corpuscles. The inexperienced observer must be careful not to mistake a well-marked and peculiarly light central depression in the corpuscle for the nucleus. In all doubtful cases, of course, the smear must be stained and examined.

Examination of the Blood in Reference to the Formation of Rouleaux

Under normal conditions, in fresh microscopic blood-specimens which are not too thin, we find the red blood-corpuscles, as a result of their peculiar disk-like shape and the viscosity of the blood, standing upon their edges and arranged in cylindric conglomerations which have been compared to a roll of coins. This formation occurs in the circulation only when the blood stagnates, but it normally occurs quite rapidly (in a few seconds) outside of the body. This process is known as the formation of rouleaux. It is evident that the formation of rouleaux must be influenced by the number of the red blood-corpuscles. We consequently find a diminished formation of rouleaux in all conditions which are associated with a diminution in the number of the red blood-corpuscles, and with a properly made specimen the diminished tendency to form rouleaux may be made the basis of a probable diagnosis of a decreased number of red blood-cells. By a properly prepared specimen is meant one having a sufficient thickness to allow the erythrocytes to stand upon their edges. If the preparation be too thin, the erythrocytes are flattened out by the cover-glass and cannot adhere to each other by their flat surfaces. When a specimen of proper thickness is immediately examined, individual erythrocytes should be visible standing upon their edges. In order to obtain a layer of blood of the requisite depth, we should vary the size of the drop of blood upon the slide and avoid exerting any pressure upon the cover-glass. The specimen should not be too thick, since this interferes not only with the formation of rouleaux, but also with their recognition. Poikilocytosis, as well as a diminished number of erythrocytes, naturally tends to prevent the formation of rouleaux. From our investigations thus far we cannot say whether the formation of rouleaux is disturbed by a diminished viscosity of the blood.

Microscopic Determination of the Amount of Fibrin in the Blood

In addition to the quantitative estimation of the separated and purified fibrin from a given quantity of blood,¹ the microscopic examination of a fresh blood-specimen may sometimes give a fair idea of the amount of contained fibrin. If a fresh blood-specimen be protected against drying by smearing the edges of the cover-glass with paraffin, and be allowed to stand for a quarter or a half-hour, the separated fibrin may be recognized by strong magnification in the shape of a fine network more or less distinctly spread out between the red blood-corpuscles. In order to form a conception of the quantity of fibrin present, the thickness of the specimen must be

¹ After washing the clot with chloroform water, alcohol, and ether, the quantitative estimation may be made either by weighing or by Kjeldahl's method.

considered, since, other things being equal, the thicker the specimen, the more marked will be the fibrin network. If the specimen be very thin, the fibrin network may entirely escape observation. A place in the specimen should consequently be selected which fulfils the requirements laid down for the examination of the blood for rouleaux (see above), *i. e.*, immediate observation should reveal isolated red blood-cells standing upon their edges, and, subsequently, distinct spaces should be seen between well-formed rouleaux. When the blood is rich in fibrin, as in inflammatory affections and particularly in pneumonia, the spaces between the rouleaux are entirely filled by a thick fibrin network; while if the blood contain but little fibrin, it is concentrated about the collections of blood-platelets, in the shape of poorly formed stars. In general the quantity of fibrin in the blood goes hand in hand with the degree of leukocytosis; and in leukopenic diseases, such as typhoid fever, a pronounced diminution of the amount of fibrin is consequently not without diagnostic importance.

PREPARATION AND STAINING OF DRIED SPECIMENS

The staining of the histologic elements of the blood is almost exclusively confined to dry preparations. These stained specimens give information in regard to the granulation of the leukocyte protoplasm discovered by Ehrlich, as well as to the coarser morphologic conditions and staining properties of the nuclei and of the protoplasm of all the blood-cells. Ehrlich, by a careful study of the staining peculiarities of the granulations with various anilin colors, has found that with given mixtures of anilin dyes they possess elective affinities and stain differently. He classifies the available anilin dyes, which are chemical salts, into an *acid group*, in which the acid radicle, and a *basic group*, in which the basic radicle, determines the staining property of the dye, and further into a *neutral group*, in which both radicles possess staining properties. *Eosin* and *acid fuchsin* are types of acid stains, *methylen-blue* and *methylen-green* of basic stains, and *rosanilin* and *picric acid* of neutral stains.

He found that certain granulations in the white blood-corpuscles stained only with acid, others only with basic, stains; a third group could be stained with both dyes, and a fourth by neutral pigments only. On the strength of this he distinguishes (α) oxyphilic or eosinophilic, (β) amphophilic, (γ and δ) basophilic, (ϵ) neutrophilic granulations. The difference between γ and δ is chiefly in the size of the granules. The (γ) granules are the so-called *mast-cell granules*; they are basophilic and larger than all the others. According to Ehrlich, each leukocyte normally contains only one kind of granule. Exceptions to this rule occur in pathologic cases. (See p. 836.) The β and δ varieties are not found in human blood.

Preparation of the Dry Blood-smear

The blood must first be spread in a thin, uniform layer on a glass slide and allowed to dry. Formerly cover-glasses exclusively were used for this purpose, but more recently slides have been employed with considerable advantage, on account of their larger size. Very thin cover-slips (less than 0.1 mm.) should be cleansed with the utmost care. Fat can be removed with a mixture of ether and alcohol and a soft linen cloth without shreds.¹ The cover-glass must be of room temperature when used, for if too cold, vapor will condense on it and easily spoil the smear. For handling the cover-glass Ehrlich's "forceps"

[¹ Soap and hot water and careful rubbing with a soft linen cloth will cleanse them thoroughly. Occasionally it may be necessary to wash new cover-slips in strong acid to remove the glaze.—Ed.]

(a clasp with broad, almost knife-like edge) is recommended. By means of this a cover-glass can be readily picked up from a perfectly flat surface. A number of cover-glasses, sufficient for several blood examinations, are usually prepared beforehand, and are placed in the ordinary dust-free cover-glass case, in which they are easily carried about. In subsequent manipulations the cover-slips should be touched only with dry finger-tips or with forceps, and best at the corner. A very minute drop of fresh blood from the tip of a finger or the lobe of the ear is touched to a cover-slip, and a second cover-slip laid on top of this without pressure. Within a few moments, by capillary action, the blood will spread out between the cover-slips in a uniform layer; then, without exerting any pressure, the slips can be *slid* rapidly apart and dried in the air. Care should be taken not to breathe upon the cover-slip, otherwise the preparation may be spoiled.

To prepare a dry smear on a slide we must have the same regard for absolute cleanliness. For smearing the blood, a carefully cleaned cover-glass is used, and in order to obtain an even smear, it is best to use the ground cover-glass supplied with the counting chamber. (See p. 755.) The method of procedure is as follows: Place in the middle of one edge of a cover-glass a very small drop of fresh blood, not much larger than the head of a pin, holding the cover-glass meanwhile by the opposite edge. The edge of the cover-glass holding the drop is brought into

Fig. 306.—Preparation of dried smears on slides.

contact at an acute angle (as shown in Fig. 306), with the upper surface of the slide as it lies flat on a table. The blood spreads by capillarity along the entire edge of the cover-glass in the acute angle between it and the slide. The cover-glass should now be moved with moderate speed in the direction of the arrow in Fig. 306, *i. e.*, away from the acute angle along the surface of the slide.¹ In this way an almost instantly dried thin blood-smear is obtained, which is preferable to the cover-glass smears, both on account of the large surface as well as the uniformity of the layer. This uniformity of the smear, as well as the possibility, in a differential leukocyte count, of being able to count in one smear a large number of leukocytes on account of the large area, in the author's opinion assures for the future the slide method of obtaining smears. Besides this, the preparations on slides have the advantage that they can be more easily carried and are much less breakable. The clean slides, or those already used for smears, are carried in a dust-proof case with separate divisions. Such cases are easily obtained from any dealer in microscopic supplies. The method of staining slide preparations is practically the same as that for the cover-glass specimens. The author describes in the following paragraphs any special procedures employed.

¹ If one smear the blood in a direction opposite to that indicated by the arrow, the corpuscles are injured as a result of the pressure by the cover-glass.

Fixation of Dried Smears

Fixing or hardening of the dry preparation can be accomplished by drying in the air, or, according to Ehrlich's original method, by heating in an incubator at 110° to 120° C. for several minutes up to several hours, according to the stain used.

The Victor Meyer toluol oven is especially well adapted for this. It consists of a double-walled copper chamber, the jacket of which is three-quarters filled with toluol. The toluol is brought to boiling, and the apparatus is so arranged that the toluol vapor is condensed by being cooled with flowing water. The temperature of the inner chamber is that of the boiling-point of toluol (111° C. with normal barometric pressure), and it cannot be exceeded. We must carefully watch the cooling of the vapor in order to avoid fire. To obtain a gradual heating by this method it is advisable not to place the cover-glass directly upon the metallic portion of the inner chamber, for it will then immediately take on the temperature of the oven; it should be placed in the oven on a slide at room temperature, in which case the heating will be more gradual and more general. In employing slide smears this occurs without any special precautions, for here the preparation can only take up the temperature of the oven gradually. The heating can be kept up, according to the method of staining employed, from one minute to one or more hours. If a higher temperature than that obtainable by toluol (111° C.) be required for fixation, the oven may be filled with xylol (boiling-point, 139° C.), or with oil of turpentine (boiling-point, 150° C.), or with a glycerin-and-water mixture (boiling-point pure glycerin, 290° C.). In general, one can substitute for the higher temperatures a lower temperature for a longer period of time.

A simpler method later recommended by Ehrlich is to place a copper plate horizontally upon a stand, and to heat one end with a flame. After a short time each individual portion of the plate will remain at a uniform temperature, the part nearest the flame hottest, the more distant portions less so. The spot upon the plate is determined where a drop of oil of toluol just boils, without presenting *Leidenfrost's phenomenon*.¹ The cover-glass, after being dried in the air, is placed at this spot. The temperature is about 111° C. (with barometer, 760 mm.). It should remain here from one-half to one minute if ordinary stains (hematoxylin, eosin, triacid) are to be used. With many other stains the cover-slip must be left there longer or a higher temperature employed.

Rubinstein² recommends more intense heat even for the triple stain. For this purpose he places the cover-slip face down for one-half to three-quarters of a minute, at a spot on the copper plate where a drop of water still shows Leidenfrost's phenomenon, and in such a way that a corner of the glass reaches over toward the cooler end of the plate.

This method of fixation acts more strongly than that in which toluol is employed as above described, and gives, according to Rubinstein (for triacid), more beautiful and constant results.

There are, however, objections to the use of the copper plate in fixation, for if it be used at high temperature, the time for fixing a cover-glass smear is so short that the errors of fixation may become very numerous if the time of fixation be allowed to vary in the slightest degree. On the other hand, the plate is less adapted for

¹ The drop runs around without wetting the copper.

² Zeit. f. wiss. Mikros., 1897, vol. xiv, p. 456.

uniform fixation at lower temperatures, with long-continued action, because the temperature of the plate varies considerably during a period of time over a very few minutes. The upper surface of the plate eventually oxidizes and becomes uneven, and as the cover-glass does not then lie flat on the metal, the action of heat is considerably altered and the duration of the period of fixation must be modified accordingly. The author does not, therefore, recommend the copper plate method, for concordant results are obtained only by those who are devoting their entire time to this work and have consequently attained a certain facility in handling the plate. He does, however, recommend the toluol oven for general use.

The fixation depends not only upon the stain employed, but also upon the strength of the stain, and the latter varies with age, so that no absolute rule can be laid down, and frequently a satisfactory result is obtained only after several trials. In general, it can be said that weaker fixation is sufficient for eosin-hematoxylin and eosin-methylene-blue (Jenner, May-Grünwald), as well as for the Giemsa stain, while a stronger fixation is necessary for Ehrlich's triacid stain (at the boiling-point of xylol, or at the point of Leidenfrost's phenomenon of water on the copper plate for one-half to one minute, one to two hours in toluol oven, or one-quarter of an hour in the xylol oven).

Preparations may also be fixed by immersing them for five minutes in absolute methyl-alcohol, or by immersing them in a 1 per cent. solution of formalin for about one minute. With the latter, however, and with acetone the author has never had good results. Since methyl-alcohol is very hygroscopic, the fixation should be carried on in vessels with air-tight stoppers.

We must also mention here the method of fixation by osmium vapor, described on p. 682, and found by Posner to be useful for blood-smears as well as urine sediment. The author, however, still lacks several facts regarding the usefulness of this last method. After fixation, the staining of the dry smear may be postponed for some time,—one to two days,—but it is better to avoid such long delay if possible.

GENERAL REMARKS ON STAINING AND EXAMINING OF DRY SMEARS

The dry smears may be stained either by single dyes, as methylene-blue, hematoxylin, or eosin, or in several colors, by the successive action of different dyes, or by different dyes made up in mixtures or in chemical combination. In the latter case a polychromatic picture is obtained by one staining process. The method of combined stains has been adopted more and more on account of the beautiful pictures which they produce. They accomplish more than the stain made up of a single dye, are less influenced by varying conditions, and are easier than any of the successive staining methods. To stain a cover-glass smear, we can either place the fixed smear in a glass containing the stain, or if we wish to save the stain, the glass is placed in the bottom of a watch-glass with the smear side downward, and the stain is allowed to flow under it, or the cover-glass can be taken up in a Cornet clamp while lying on the table and held horizontally, the stain being dropped on the smear. This latter procedure can be employed only for staining processes of short duration, for the stain would eventually evaporate, with the formation of a precipitate which would destroy the specimen. In staining preparations on a slide we can either place the slide in the stain or drop the stain on the slide, according to the time required for staining. In the former case, to prevent precipitation, we place the slide vertically in

a tall glass, or, even better, place it smear side down on the staining solution, or we can place it horizontally, supported at both ends on small pieces of glass in a dish with the smear side down, so that the solution touches only the smear surface. It is more convenient and more economic to drop the stain on the slide when only a short time is needed for staining. Peculiarities in the technic of staining (as, for instance, in staining with the Giemsa solution) should be carried out according to the directions given for the individual methods. After staining, the blood preparations are generally washed in water, then dried with filter-paper, the drying being completed by leaving them for a moment in the air at room temperature or near a flame. They are then either examined in xylol or, if the preparation is to be saved, mounted in neutral Canada balsam. Smears are generally examined with an immersion lens, using a widely opened diaphragm. In using slide smears it is unnecessary to cover the smear with a glass for the purpose of examination, for the immersion oil can be placed directly upon the smear. To preserve for further use the immersion oil can be washed off with xylol, which dries quickly, and the specimen either mounted in Canada balsam, or put aside dry, without any covering. These dry, uncovered smears are more durable than those mounted in Canada balsam.

The dyes used in blood-staining should be obtained from the firm of Grübler, chemical laboratory, Bayrische Strasse, Leipsic, because it has specialized in these products, and very nearly approaches a faultless manufacture of dye-stuffs. In reference to the theory of staining, the author recommends Ehrlich's original paper¹ in the *Encyclopedia of Microscopic Technic* by Ehrlich, Krause, Mosse, and Rosen (Berlin, 1903), and the outline on the chemistry of dyes by Pappenheim (Berlin, 1901). The author describes in the following paragraph only the best of the countless numbers of recent methods for staining the blood that have been used in his clinic, and earnestly advises those who undertake to learn the technic of blood-staining, to limit themselves to these methods as they suffice for all that has, up to the present time, been found in the blood by means of stains. The continuous experimenting with new methods which have no advantage over those that are older and more tried has caused immeasurable harm, for it has frequently led to totally erroneous explanations of blood-findings and to much confusion as regards the designating of the individual elements of the blood, which are usually easily understood and recognized with the older tried methods.

Rieder's Eosin-hematoxylin Stain.—A simple method, which usually suffices for recognizing the coarser relations, consists in immersing the specimen in a saturated solution of eosin in 5 per cent. carbolglycerin for several hours (Rieder). The color is then washed off with water, and it is counterstained for a minute with 50 per cent. Delafield's hematoxylin.² After repeated washings, the preparation is dried in the air and mounted in Canada balsam. The red blood-corpuscles and eosinophilic granules are stained red, nuclei and cell membranes dark blue, and the protoplasm of the white cells violet or reddish. (See Pl. 8, Figs. 4 and 5.)

¹ Especially Ehrlich, *Farbenanalytische Untersuchung zur Histologie und Klinik des Blutes*, Berlin, 1891.

² Two solutions: (a) 1 gm. of a crystalline hematoxylin dissolved in 6 cc. of absolute alcohol; (b) 15 gm. of alum ammoniate dissolved in 100 cc. of distilled water, and filtered after cooling. These solutions are mixed in an open dish, and exposed to light three days. The mixture is then filtered, and mixed with 25 cc. of pure glycerin and 25 cc. of methyl-alcohol. After three days this mixture is filtered and kept in stock.

To recognize the finer details of the nuclear structure, and especially of the mitoses, Rieder recommends that blood-films be first fixed, and then immersed in a saturated aqueous solution of picric acid. They should then be washed for one or two days in running water, and stained several hours with a very dilute Delafield hematoxylin; then washed in water again, and finally in water containing hydrochloric acid, dried in the air, and mounted in Canada balsam.

Ehrlich's triacid stain is usually employed when examining for Ehrlich's granules. This is prepared in the following way:

Saturated aqueous solution of orange-G, 120 to 125 cc.; saturated aqueous solution of acid fuchsin, 80 to 165 cc.; saturated aqueous solution of methylene-green, 125 cc.; water, 300 cc.; absolute alcohol, 200 cc.; glycerin, 100 cc.

These solutions are generally dropped on the fixed, dry smear. To stain cover-glass preparations, and at the same time to prevent precipitation, Rubenstein places a drop of the triacid solution on a slide and lays the fixed smear down on it. After staining from five to seven minutes, the smear is washed in water, dried with filter-paper, and mounted in Canada balsam.

Precipitates almost always form in time in triacid solution, and if any of the precipitate be placed on the smear, it interferes with the picture. It is, therefore, advisable to avoid shaking up the bottle containing the triacid solution, and it is better to take the solution from the bottle by means of a finely drawn pipet and drop it on the smear. Rubenstein's method, described above, also prevents the disturbing action of the precipitate to a large extent. By frequent filtering the staining power of the solution may be diminished, and rather than filter, therefore, it is advisable to allow the solution to stand for a few days until the precipitate settles, if in any way it was accidentally shaken up.

Plate 6 shows the various elements of the blood stained with triacid.

The neutrophile granules appear most beautifully stained with triacid. The hemoglobin takes on an orange to a brownish color (Pl. 6, Fig. 1, No. 8). The nuclei are bluish green; the neutrophile (ϵ) granules violet (Pl. 6, Fig. 1, No. 1); the eosinophile (α) granules copper colored (Pl. 6, Fig. 1, No. 2). The protoplasm of the lymphocytes and large mononuclear cells is unstained, or after strong fixation, a pale pink (Pl. 6, Fig. 1, Nos. 5-7). The basophile granules of the red blood-cells are unstained, just as the basophile granules in leukocytes. The latter can at times be recognized as colorless spaces (Pl. 6, Fig. 1, No. 3). The large mononuclear cells often show a light, violet-reddish, neutrophile granulation. (See p. 789.)

Successful triacid smears can be obtained only after strong fixation, either by long-continued hardening in methyl-alcohol or by strong heat fixation. (See p. 774.) The triacid solution is, on the whole, durable. Solutions which are too old, however, frequently act improperly, and must then be replaced by fresh ones.

The author cannot here sufficiently emphasize the importance of using the triacid solution in all doubtful cases. As regards the determination of neutrophile granules, which are equally important clinically as well as physiologically, the triacid stain is second to none, and the replacement of this stain by the newer ones, such as Jenner's and Giemsa's, which require less fixation, has led to many erroneous results, inasmuch as these methods, though they frequently give good results, may, as in some cases in the author's experience, leave one in doubt, for as yet unknown reasons, since they do not bring out the neutrophile granules clearly enough. This frequently leads clinical assistants with little experience to totally erroneous results, since, for instance, lymphocytes and myelocytes may be mistaken for one another, or it may be assumed that the neutrophile cells or the myelocytes are deficient in neutrophile granules, etc. For these reasons, in a clinic where assistants with little experience often work, the rules for triacid staining must be implicitly adhered to and the technic must be thoroughly mastered.

Panoptic Triacid Stains and Nuclear After-staining of Triacid Preparations.—Since the nuclei in triacid preparations appear but slightly stained, Pappenheim¹ has described a so-called panoptic triacid mixture, in which the methyl-green is replaced by methylene-blue. This can be obtained from Dr. Grüber in Leipsic, in a solution ready for use. By means of this solution the nuclei are better stained; the granules are, however, not so distinct as with the original triacid. It is, therefore, recommended to restrain the Ehrlich triacid preparation with a dilute 0.25 per cent. watery methylene-blue solution in case a better nuclear stain be desired. We then obtain a good staining of mast-cell granules, besides a good nuclear stain.

Staining the Blood with Methylene-blue.—As a stain we may use a 0.25 to 0.50 per cent. watery methylene-blue solution (methylene-blue "pure," Höchst) or Löffler's alkaline methylene-blue, which can be obtained by mixing 0.5 gm.

¹ Deut. med. Woch., 1901, No. 46.

methylene-blue in 30 gm. of alcohol with 1 cc. of a 1 per cent. potassium hydronid solution and 100 cc. of water. Well-fixed preparations are stained only for a short time (about five seconds) in using Löffler's methylene-blue, and then immediately washed off with water. The methylene-blue also serves for the determination of bacteria and malarial plasmodia (see p. 818), and especially for the recognition of polychromatophilia and basophilic granulation of the red blood-cells. While the normal red blood-cells appear yellowish green after proper fixation, the polychromatophilic cells present may be recognized by their greenish-blue or even pure blue shade. The term polychromatophilia is not strictly correct in speaking of the preparations stained with a single dye: one should rather speak of a more or less high grade of basophilia. The red blood-cells containing basophile granules appear with pure methylene-blue stain, dotted with blue, as is the case with the combined stains (Pl. 4, Fig. 4, *a*, et seq., and Pl. 5, Fig. 2, No. 27); but the granules seem to rise up from a yellowish-green rather than reddish background. The neutrophile and eosinophile granules of the leukocytes are unstained, the basophile granules blue, or with certain varieties of methylene-blue they are violet. (See Giemsa's stain.)

The Jenner Stain.—This method has been largely adopted because of its convenience, since with it special fixation before staining is unnecessary. It depends upon the employment of a chemical compound of methylene-blue as a base and eosin as an acid. This compound stains the blood elements more or less selectively, partly blue, partly red, and partly with a mixed color. There is practically no difference between Jenner's original method and that employed by May and Grünwald. The methods of procedure which have led up to the use of the combination stain are to be found in the older editions of this work, and cannot be entered into here, but the author recommends in this connection the work of Türk.¹ The possibility of staining smears without previous fixation depends upon the fact that the dye is dissolved in methyl-alcohol, and dyeing and fixing occur, therefore, at the same time. The dye may be obtained from Grüber, either in powdered form or solution. Burroughs, Wellcome & Co., of London, also prepare compressed tablets of this, which are to be dissolved in 10 cc. of methyl-alcohol. If the powder be used, 0.3 gm. should be dissolved in 100 cc. chemically pure absolute methyl-alcohol. As methyl-alcohol cannot always be obtained pure, the author recommends Dr. Grüber's stock solutions.

According to Jenner's original directions, the stain is dropped on the unfixed, air-dried, and, for the best results, freshest possible smear. If a cover-glass be used, it should be held in a Cornet clasp. After allowing the stain to remain on for two to three minutes, the preparation is rinsed in distilled water for five to ten seconds, until the color of the smear is pink. The preparation is now dried quickly with filter-paper, then with slight heat, and mounted in Canada balsam, or if it be a slide preparation, examined directly in cedar oil. In older smears, or in those that stain with difficulty, the author recommends that the specimen be first fixed in absolute methyl-alcohol for ten to twenty minutes; then stained with a mixture of 1 part stain and 2 parts distilled water for five to fifteen minutes; then proceed as above. If the staining cannot be undertaken immediately after fixation, the author suggests that the preparation be dried and put in a desiccator over calcium chlorid, *i. e.*, kept absolutely dry until staining is begun.

To eliminate certain difficulties which arise at times in the Jenner method the technic has been modified so that after three minutes' fixing and staining with the concentrated solution an equal amount of distilled water is added and staining is continued for five to fifteen minutes. Then proceed as above. A further modification of the Jenner technic, that of Assman, Jr., has given very good results in the author's clinic. The directions are as follows:

(1) Place the slide with the blood-smear still unfixed in a perfectly clean Petri dish and cover with 40 drops of the methyl-alcohol stain, so that the latter does not overflow the edge of the slide. This is left on the smear for three minutes for purposes of fixation.

(2) Add 20 cc. of distilled water to which 5 drops of a 1 per cent. potassium carbonate solution has been added, and shake the dish until a uniformly clear, light-violet, watery solution is obtained which is free from precipitate; allow this staining process to go on for five minutes.

(3) Remove the preparation and dry without further rinsing. Place in Canada balsam, or, if a slide preparation, examine directly in cedar oil.

The smears pictured in Pl. 4 and Pl. 5, Fig. 1, are stained according to Jenner. In general, if well done, they are not at all inferior to the triacid preparations. One

¹ Türk, Vorlesungen über klinische Hämatologie, Wien, 1904.

advantage over the triacid is that they show a good nuclear stain of the leukocytes and red blood-cells. The basophilic granulations of the leukocytes appear deep blue (just the opposite of the triacid stain) (Pl. 4, Fig. 2, *g*, and Pl. 5, Fig. 1, *e*), or frequently, depending upon the dye used in the preparation of the solution, even metachromatic violet, on account of the azure content of the methylene-blue. (See Giemsa's stain.) The neutrophile granules of the leukocytes are stained reddish violet (Pl. 4 and 5, Fig. 1), and we readily recognize, from their bluish tint, the polychromatophilic red blood-cells and the deep-blue basophile granulations of the "stippled" erythrocytes (Pl. 4, Fig. 4, *a*, etc.). The normoblasts (Pl. 4, Fig. 4, *b*, and Pl. 5, Fig. 1, *h*) show an intensely stained black-blue nucleus, while in the megaloblasts it is a paler blue (Pl. 4, Fig. 4, *d*, and Fig. 1, *g*). The nucleus of the lymphocytes (Pl. 4, Fig. 4, *h-n*) appears darker when weakly fixed, and lighter when strongly fixed, than the surrounding protoplasm (Pl. 5, Fig. 1, *g*). The large mononuclear cells show a slightly basophilic protoplasmic reticulum (Pl. 4, Fig. 40).

In spite of the advantage of good Jenner's preparations, the author states that the advantage of this procedure cannot always be realized, for some unknown reason. There are cases where, probably on account of the stain or the preparation of the smear, the neutrophile granules are unstained or insufficiently stained, in which case they are of a bluish shade, and cannot be readily distinguished from the surrounding protoplasm. The experienced worker will, without further ado, discard this smear in these cases and resort to the triacid stain. With the inexperienced worker, however, the use of such preparations may give deceptive results, on account of the insufficient staining of the neutrophile substance, with consequent confusing of neutrophile and basophile granules. This peculiarity of the stain prevents its universal employment, and for this reason the author recommends supplementing the Jenner by the triacid stain, in cases of even the slightest doubt. Frequently the above-mentioned faults of the Jenner method can be eliminated by energetic heat fixation before staining (ten minutes to one hour in the toluol oven). In many cases the author obtained satisfactory results in this way. By strong fixation we bring about the ready recognition of the lymphocytes and their differentiation from the large mononuclear cells, for in strongly fixed preparations the protoplasm of the lymphocytes is stained more deeply with methylene-blue than the nucleus, while the large mononuclear cells behave exactly the opposite. The difference in the nucleated red blood-cells is also brought out. (See pp. 788 and 789.)

Giemsa's Stain.—There are certain forms of methylene-blue that are not strictly pure, but contain, in addition, a red dye. Romanowski first made use of this kind of methylene-blue especially for the staining of malarial plasmodia. This dye, however, gave uncertain and unreliable results until Giemsa employed it as the so-called azure dye (which is obtained from methylene-blue by the special method of Michaelis) in combination with eosin and methylene-blue. This is the dye which in older methylene-blue and certain Jenner solutions showed the metachromatic violet stain of the mast-cell granules. The Giemsa solution is made up of methylene azure with eosin and methylene-blue in alcohol and glycerin. It is quite difficult to prepare it, and it is better to obtain a stock solution from Dr. Grübler in Leipsic. The staining is carried out as follows: the air-dried smear is fixed for one-half hour in absolute alcohol, preferably absolute methyl-alcohol. A dilution of the Giemsa solution is then prepared just before using by mixing 4 drops of the solution in 4 cc. of distilled water at 40° C. The smear is then covered with the uncooled solution, which is left on for thirty minutes. The solution being warm at first, the most favorable time is used for fixing the smear, as some of the dye is precipitated during cooling. In order to avoid these interfering precipitates it is better to place the cover-glass preparation in a watch-glass or a concave dish, with the smear face downward in stain, for in this way the precipitate cannot settle on its surface. Similarly, it is recommended that the smears on slides be placed with the diluted and warm solutions in a covered Petri dish, with the smear on the under surface, the ends of the slide resting on fragments of glass. In this way a faultless specimen is obtained. After the staining is complete, the preparation is rinsed in water, dried with blotting-paper, then with slight heat, and, if a cover-glass, mounted in neutral Canada balsam, or if it be a slide preparation, examined directly with the immersion lens in cedar oil without a cover-glass. The Giemsa stain (see Pl. 5, Figs. 2 and 3) gives generally beautiful panoptic views, which do not, however, have such markedly different colors as either the Jenner or triacid stain, but it suffices for diagnostic purposes, and in a differential leukocyte count offers the advantage of a very intense staining of the white cells. (See p. 794.) The most

important blood elements are shown with the Giemsa stain in Pl. 5, Figs. 2 and 3. The nuclei appear violet, the mast-cell granules partly unstained, partly violet black (Pl. 5, Fig. 2, Nos. 3 and 4), the basophile granules of the red blood-corpuscles are blue (Pl. 5, Fig. 3, No. 27), the neutrophile granules of the polynuclear leukocytes are pale to dark violet (Pl. 5, Fig. 2, No. 1), the eosinophile granules are red (Pl. 5, Fig. 2, No. 2), the protoplasm of the lymphocytes and transition cells (Pl. 5, Fig. 2, Nos. 10-13 and 5 and 6) is blue to violet, that of the large mononuclears, blue to bluish violet (Pl. 5, Fig. 2, Nos. 7-9), the red blood-corpuscles reddish, the polychromatophilic red cells are bluish red (Pl. 5, Fig. 3, Nos. 26 and 28). The azurophilic granules visible with this stain as violet to red dots in many lymphocytes are particularly confusing to beginners (Pl. 5, Fig. 2, No. 10), and may lead to mistaking myelocytes for lymphocytes.

The Giemsa method, like the Jenner, is somewhat unreliable as regards the staining of neutrophile granules. The author believes that the Giemsa method is very useful, but that it can in no way replace the others, as being universally preferable, and that it is one in which the inexperienced must observe certain precautions.

Leishman's Stain.¹—In principle this is the same as Giemsa's, and has the advantage that it is easier and can be carried out more quickly. A stock Leishman stain, containing methylene-blue, eosin, and azure, can be obtained from Dr. Grüber, or can be prepared by dissolving 0.2 gm. of the powdered dye, or one of the tablets prepared commercially by Burroughs, Wellcome & Co., of London, in 10 cc. of absolute methyl-alcohol. Fixation is accomplished at the same time as the staining by the methyl-alcohol, just as with the Jenner stain. The technic is as follows: The air-dried, unstained smear is covered with the stain. After one minute an equal up to double the quantity of distilled water is added and is carefully mixed by gently moving the slide backward and forward. The diluted solution is left on the smear for five minutes, washed with ordinary water, dried with blotting- or filter-paper, then with gentle heat, and mounted in Canada balsam or examined in cedar oil.

The results from the Leishman stain are just the same as with the Giemsa method, only the basophile granules of the mast-cells are more constantly stained on account of the alcoholic solution of the dye. The ideas of the author as regards the exclusive use of the Giemsa method are also applicable here. (See above, Giemsa's Stain.) Excellent smears stained exactly according to Leishman are shown in large numbers in the Atlas of Blood Diseases by Schleip (Berlin, 1907, Urban and Schwarzenberg).

The Pyronin Methyl-green Stain of Pappenheim.²—A stock stain can be obtained from Dr. Grüber. It contains two basic dyes of different combining powers. Pyronin is a much stronger base than methyl-green. It stains red the strongly basophile substances, as the protoplasm of lymphocytes and Türk's irritation forms (plasma cells), and, according to Nägeli, the small myeloblasts, as well as the strongly polychromatophilic red blood-cells. According to Nägeli, a cell is not a lymphocyte unless its protoplasm stains red with pyronin, but it does not hold that all cells whose protoplasm is red are lymphocytes. Smears treated with pyronin methyl-green are best fixed by heat, then stained for five minutes with the prepared dye, washed off, dried, and mounted in Canada balsam, or examined directly in cedar oil.

[Hastings³ has devised a permanent Nocht stain which is used in solution in methylic alcohol. The preparation of the staining fluid is somewhat difficult. It had best be secured from Ernst Leitz, 30 East 18th St., New York City.

To use the stain no previous fixation is necessary. The dried smear is flooded with the staining fluid for one minute; the solution is then diluted with 5 to 7 drops of water; and this diluted stain is allowed to act for five minutes. The specimen is then washed in distilled water, care being taken to clean off the negative side of the glass upon which a precipitate collects, blotted with filter paper and examined directly or mounted in balsam.

All the leukocyte granulations are well differentiated. The granular basophilic and polychromatophilic changes in the red cells are well shown, and the blood-plates stain clearly.—Ed.]

IODIN REACTION AND GLYCOGEN CONTENT OF THE LEUKOCYTES

Ehrlich's methods are the best for demonstrating the *microscopic iodine reaction of the blood*. The dried blood-film (which must, however, not be heated) is immersed in a solution of iodine and gum arabic (iodine 1, potassium iodide 3, water 50, and enough gum arabic to render the fluid thick). Ehrlich¹ has since announced that it is an advantage to substitute iodine itself for the solution of iodine. This is done by placing the preparations dried in the air under a closed glass containing crystals of iodine for several minutes, until the color is dark brown. The preparation should then be examined in a saturated syrupy solution of levulose; and to preserve it, should be surrounded with varnish. The color of the leukocytes varies in individual cases. The red blood-cells are stained diffusely brown, although this, at present at least, has no special interest. Zollikofer has established the following facts with regard to the leukocytes.² Under physiologic conditions, brown-stained protoplasmic granules are found most frequently in lymphocytes, oftentimes in mast-cells, and exceptionally in the large mononuclear cells; the polynuclear neutrophilic cells are faintly stained brown. A distinct deposit of brown-stained granules and flakes in the last-mentioned cells is considered pathologic. This condition is the one which writers have paid most attention to up to the present time. It is ordinarily spoken of as the *iodine reaction* of the leukocytes or the *intracellular iodine reaction of the blood*. Zollikofer's brown granules are very rarely found in eosinophiles, and then under conditions which are not understood or defined. They are never found in the neutrophilic mononuclear cells (myelocytes). Ehrlich³ has also described a so-called extracellular reaction, in which stained brown, granular masses are found outside of the leukocytes. Gabritschewski⁴ and Zollikofer have shown, however, that these formations are blood-plates, which, under conditions not definitely known, give the iodine reaction, at times in normal blood, at times under pathologic conditions, especially in diabetes mellitus. This reaction does not necessarily accompany the intracellular reaction.

According to the findings of Zollikofer, it has been conclusively shown that if iodine vapor be allowed to act on moist smears, the iodine reaction is greatly increased, so that in perfectly normal blood we may find fine brown granules instead of the diffuse light-brownish color in the neutrophile leukocytes. The absence of these normal granules in dry smears treated with iodine is due, according to Zollikofer, to the destruction of the granules in the normal cells occasioned by the drying. In pathologic accumulations of this iodine-staining substance the destruction of the granules by drying is not sufficient to make them disappear entirely. The term "positive iodine reaction," or "iodophilia," can, therefore, only be employed in expressing the results on dry smears obtained by Ehrlich's method, as above described.

This brown-staining substance is generally supposed (and by Ehrlich, too) to be glycogen. But Czerny,⁵ Kamminer,⁶ and especially Zollikofer, discredit this theory. Very likely it is related to amyloid. Under certain conditions it is stained violet and not brown by iodine, which favors this latter view.

The pathologic iodine reaction, at present at least, applies only to the appearance of brown-stained granules in the polynuclear neutrophiles. Very little can be said as yet in regard to the clinical significance of this "iodine reaction." It is almost always present with *leukocytosis*, especially in purulent conditions, but not, for instance, in erysipelas.

According to the investigations of Zollikofer in the Bern Clinic, the presence of this reaction (*e. g.*, in appendicitis) does not always prove the presence of pus, neither does its absence exclude the presence of pus. About the same results were observed in cases which recovered spontaneously and in those which came to operation. No definite conclusions can be drawn from the absence or presence of the iodine reaction in diabetes mellitus, although several observations of Zollikofer's would seem to indicate that a diminution of diabetic acidosis is associated with diminution of the reaction. It was thought that the reaction might possibly be used in the diagnosis of amyloid degeneration, an opinion based upon the observations of Czerny relative to the presence of the iodine reaction in artificially produced amyloid degeneration; but observations in the author's clinic have disproved this. Zollikofer found

⁵ *Ibid.*, vol. xxxi.

⁶ *Deut. med. Woch.*, 1899, vol. xv.

that if iodine vapor acted upon moist preparations, the reaction was considerably increased, so that even in normal blood fine brown granules appeared in the neutrophilic leukocytes, instead of the diffused light-brown stain. The absence of these normal granules in the dry specimens treated with iodine is due, according to Zollikofer, to the disintegration of the granules in the interior of the cells during the process of drying.

Best's glycogen stain,¹ by means of carmin, ammonia, potassium carbonate, and methyl-alcohol, which gives wonderful results in sections, cannot, unfortunately, be employed for dry smears, according to the studies of Dr. Wegelin. This ought to be a new and important fact, according to Zollikofer and others, in differentiating the brown, iodine-staining substances of the leukocytes from the glycogen.

From the more recent observations on the clinical significance of the iodine reaction we find the following: In typhoid, the iodine reaction is negative (Hofbauer; also in malaria (Huber, Hofbauer); in articular rheumatism (Sorochowitsch), and in tuberculosis (Hofbauer), if these be not complicated by mixed infection. As a point in differential diagnosis between articular rheumatism and general gonorrheal infection it is noteworthy that the latter is attended by iodophilia (Sorochowitsch).

MICROSCOPIC EXAMINATION OF THE ALKALI DISTRIBUTION IN THE BLOOD, ACCORDING TO EHRLICH AND LAZARUS

This method² depends upon the fact that iodoeosin (the free acid) in chloroform solution will stain the alkali part of the dry blood-smear a deep red. If we place a dry blood smear without fixation in such a solution, it quickly becomes of a deep-red color. If this be now washed with chloroform and placed in Canada balsam while still moist, the plasma will appear red, the red blood-corpuscles colorless, the protoplasm of the white blood-cells red, while the nuclei will appear as colorless spaces (negative nuclear stain). Fibrin will also appear intensely red. This theoretically interesting stain has been found of but little value to date.

MICROSCOPIC APPEARANCE OF ERYTHROCYTES

(Poikilocytosis; Staining Capacity of the Red Blood-cells; Polychromatophilic Changes; Granular Basophilic Degeneration)

The red cells or erythrocytes are normally biconcave disks. Under pathologic conditions, however, they may present very abnormal shapes,

Fig. 307.—Poikilocytes in pernicious anemia.

a condition which has been called by Quincke poikilocytosis. Poikilocytes may assume any shape (see Fig. 307 and Pl. 8, a, Fig. 1, c). Their size, too, may vary considerably. Poikilocytosis is observed in all cases of *grave anemia*, especially in the so-called *pernicious types*, in *leukemia*, in the *cachexia* of *carcinoma of the stomach*, and rarely in the innocent types of anemia, such as *chlorosis*. The diagnostic significance of poikilocytosis is not so great as was formerly supposed.

It certainly is by no means pathognomonic of pernicious anemia. As a rule, the degree of poikilocytosis corresponds to the degree of oligochromemia.

Maragliano³ considers these degenerative types of red blood-cells. Thus, if normal blood be examined under a cover-glass fixed to a slide with paraffin at the temperature of about 26° to 27° C., a number of progressive changes occur in the corpuscles, and these same changes are found in the fresh blood under pathologic conditions. After thirty to seventy minutes the so-called *endoglobular changes* occur. A colorless region, irregularly outlined, develops from the center and shows

¹ Zeit. f. wiss. Mikros., 1906, vol. xxiii.

² Ehrlich and Lazarus, Anemia in Nothnagel's System.

³ Zeit. f. klin. Med., 1892, vol. xxi, p. 419.

an ameboid motion. (See Plate 7, Figs. 18-22.) Considerably later—three to four hours—so-called total alteration of the blood-cells begins, and the external shape is changed. This change commences with the formation of a thorn-apple or mulberry-like appearance, which, according to Maragliano, has incorrectly been considered to be the result of drying. The blood-corpuscles gradually become more and more deformed (ten to twelve hours); pseudopodia develop with an ameboid-like motility very much like that of the decolorized spots above described. Poikilocytes are formed in this way. Maragliano has called attention to the fact that not only poikilocytes, but all the other types of degeneration described, especially the crenated types of blood-cells, may be found in the fresh preparation of severe blood-diseases. Less serious pathologic changes of the blood manifest themselves by the fact that these changes take place outside of the body sooner than in normal blood-specimens.

These changes have diagnostic value only when they are seen in absolutely fresh specimens. Pressure on the tissues when removing the blood and on the cover-glass must be avoided, because this may produce artificial deformity of the blood-cells. On the other hand, the abnormally rapid appearance of deformity in blood apparently normal on removal indicates a certain lack of resistance of the red cells, and is not entirely without diagnostic interest. The crenated types are of especial interest in this respect, although they have not yet been studied from a clinical standpoint.

We must, however, be very careful in considering these as postmortem changes, for they may also appear in the normal blood under extremely unfavorable conditions, brought about by rapid drying. The inexperienced should, therefore, put little value on crenated forms.

BEHAVIOR OF THE ERYTHROCYTES TO STAINS; ANISOCHROMIA; POLYCHROMASIA; BASOPHILIC GRANULATION OF THE RED BLOOD-CORPUSCLES

So far as the staining capacity of the red blood-corpuscles is concerned, the dry preparations take acid stains very readily (eosin, orange-G). The intensity of this stain depends upon the amount of hemoglobin contained in the cells. This is of practical importance, because after a little practice the degree of anemia or oligochromemia can be made out from dry specimens. The difference between normal red cells and those deficient in hemoglobin is much more striking in the stained dry preparation than in unstained cells.

Unequal hemoglobin content of the individual red blood-corpuscles (anisochromia, see p. 771) can be well recognized in stained smears by the difference in the intensity of the stain of the erythrocytes.

The so-called vital staining of the red blood-corpuscles with certain dyes, *e. g.*, neutral red, which can be carried out by adding the stain directly to the fresh smear, depends apparently upon the degeneration of the red blood-corpuscles. Since they have no practical value, these so-called vital stainings, which are in no sense vital, cannot be discussed here. Living red blood-corpuscles are achromatophilic and cannot be stained by any dye. If the red blood-corpuscles are fixed by drying and heating, they take up the eosin and chemically related (acid) dyes.

Degeneration of the red cells described by Maragliano may be demonstrated by staining. (See p. 782.) Endoglobular degenerated blood-cells devoid of color in the center (see above) do not act in this way. The decolorized portion in dry preparations stains with hematoxylin, whereas the peripheral region, containing hemoglobin, stains with eosin. To demonstrate this, the eosin-hematoxylin staining methods described upon p. 776 may be employed. The fact that the endoglobular region stains proves that it is not a vacuole, as was formerly believed, a view which is still held by some authorities.

Polychromatophilia consists in a change in the staining capacity of the red cells. Normally shaped red cells, as well as poikilocytes, which normally take the acid components from staining mixtures, are tinged with the methylene-blue (Jenner's stain, see p. 778 et seq.)

or eosin hematoxylin (p. 776) present therein, the tint varying from eosin-red, with a bluish tinge, to pure violet. Polychromatophilia is most distinctly brought out by using plain methylene-blue (see p. 778)—best, Löffler's alkaline methylene-blue after good fixation. Normal red cells then appear pale yellow or, at the most, greenish. The polychromatophiles appear green to blue.

This change has been noticed in nucleated red cells, especially the megaloblasts in pernicious anemia (see p. 787 and Plate 4, Fig. 4 c, Plate 5, Fig. 3, No. 26) and, like poikilocytosis, is found in all severe cases of anemia. Occurring under such conditions, it is suggestive of degeneration, and was, therefore, described as such by Ehrlich and Gabritschewski. This view, however, has become untenable, since we know that polychromatophilic staining is present in the early developmental stages of erythrocytes. It could be imagined quite as easily that the polychromatophilic changes were indicative of processes of regeneration.

Another peculiar change is the so-called *granular (granular basophilic) degeneration of the erythrocytes*. (Basophilic granulation, stippling of the erythrocytes.) This has been closely studied by Lazarus, Askanazy, Plehn,¹ Grawitz,² Nägeli, and others. In specimens stained with Jenner's, Giemsa's, or Leishman's solutions, or by brief immersion in Löffler's methylene-blue³ (see p. 777), some of the erythrocytes are seen to contain a number of blue to bluish-black (basophilic) granules. (See Plate 4, Fig. 4 a; Plate 5, Fig. 3, No. 27.) This change has been found chiefly in conditions associated with destruction of the erythrocytes, such as pernicious anemia, leukemia, certain forms of tropic anemia, carcinoma, chronic lead-poisoning, sepsis, and malaria. Basophilic granulation is of the greatest diagnostic importance in the recognition of chronic lead-poisoning (Nägeli). The statement of Grawitz, that granular basophilic degeneration has never been found in chlorosis, has not been confirmed. Rosin and Biber state that they have observed basophilic granules in the erythrocytes of healthy individuals. Grawitz succeeded in producing this change in mice by overheating the animals. Lazarus and Askanazy look upon the basophilic granules as the remains of disintegrated nuclei ("karyolytic fragments"), but Grawitz attributes them to degenerative changes in the stromata of the erythrocytes. Most other recent writers, on the contrary, correctly regard the basophilic granulation as a phenomenon holding some relation to the regeneration of the blood. Jawein,⁴ for instance, observed this change in a patient recovering from a bothriocephalus anemia. Nägeli also regards it as a sign of regeneration, basing his opinion on Pappenheim's demonstration of basophilic stippling in cells from normal bone-marrow, on Engel's and Schmidt's finding of the same in embryonic blood, and on his own clinical observations that in the severest grades of lead-poisoning the basophilic granules disappear, whereas, with the improvement of the anemia, they again occur. Nägeli also demonstrated that in experimental lead-poisoning in animals recovery following the use of potassium iodid is accompanied by marked basophilic stippling. It is probable that basophilic granulation is intimately related to erythrocytic polychromatophilia, with which it is so frequently associated.

The question whether the granules represent nuclear remnants or are derived from the protoplasm is not yet decided. Both suppositions are consistent with the interpretation of the change as a regenerative phenomenon.

A complete exposition of the ideas on basophile granulations of erythrocytes can be found in the article by Askanazy, from Lichtheim's clinic.⁵

The larger particles staining with methylene-blue that result from the well-known nuclear destruction in nucleated red blood-corpuscles are to be distinguished from the true basophilic granulations described above.

ERYTHROCYTIC SHADOWS [PONFICK'S SHADOW CORPUSCLES; HAYEM'S ACHROMACYTES.—Ed.]

These forms, which appear in the blood, have the shape of red blood-corpuscles, but are absolutely devoid of color, so that the central depression can no longer be distinctly recognized. They are the stromata of red blood-corpuscles which have lost their coloring-matter. They may be produced artificially if sufficient water or hypotonic salt solution to lake the red blood-corpuscles be added to normal blood. (See p. 768.) They are found pathologically wherever, by osmosis or by chemical hemolysis, red blood-corpuscles are being rapidly destroyed, as in hemoglobinuria occurring independently or as the result of poisoning with chlorate of potash or other poisons which destroy red cells. They may also be found, although in smaller numbers, in pernicious anemia. If erythrocytic shadows be present, hemoglobin may be demonstrated in the serum or plasma by adding hirudin to prevent coagulation and then centrifuging. However, the destruction of red cells may be so gradual that all free hemoglobin is straightway decomposed or excreted by the kidneys.

VARIATION IN THE SIZE OF RED BLOOD-CORPUSCLES; ANISOCYTOSIS; THE VOLUME INDEX

The true size of the erythrocytes is best determined in a fresh, unstained specimen, because drying alters their size. Even in healthy individuals the red blood-corpuscles are not all of the same size. The normal size varies, according to different authors, between 6 and 9 μ (averaging about 7). The very large cells are called giant corpuscles, or macrocytes; the small ones, microcytes. According to Gram, the red blood-corpuscles are larger in northern than in southern countries. Although slight in a normal individual, there may be very great differences in size in the same blood under pathologic conditions. This condition of the blood is called *anisocytosis*. The very large erythrocytes (9 to 16 μ in diameter) are called *giant cells*, *megalocytes*, or *macrocytes*. The very small ones (3 to 4 μ in diameter), *dwarf cells* or *microcytes*. There is a striking anisocytosis in pernicious anemia, in which macrocytes as well as microcytes are present. It has often been assumed that the latter signify the fragmentation of the poikilocytes. The presence of megalocytes, however, which depends strictly on the occurrence of megaloblasts, is particularly characteristic of this disease, and, according to Nägeli, of greater diagnostic import than poikilocytosis. Microcytes, on the contrary, play an important part in the secondary anemias and in chlorosis. In the latter disease megalocytes, if present, are usually pale, whereas in pernicious anemia they are, as a rule, dark red.

The Volume Index (Quotient or Value) of the Erythrocytes.—We are indebted to J. A. Capps¹ for an interesting study of the size of the erythrocytes. By means of the hematocrit and without dilution (see p. 766) this author has determined the volume of the erythrocytes as compared to the volume of the whole blood (cells + plasma). In normal cases he obtained a corpuscular volume of 50 per cent. If this value be regarded as 1, the volume in pathologic cases may be calculated in per cent. of the normal volume, just as is the amount of hemoglobin. Capps also counts the erythrocytes in the blood under observation, and expresses this number in per cent. by comparing it with the normal number of erythrocytes. By dividing

¹ Jour. Med. Research, 1903, vol. v and vi.

the volume of the erythrocytes by the number of the erythrocytes (both expressed in percentages) he obtains the so-called volume index of the erythrocytes, for which expression the author would suggest substituting "volume quotient" or "volume value" of the erythrocytes, analogous to the hemoglobin quotient or hemoglobin value [color index.—Ed.] of the erythrocytes. The volume index or quotient, therefore, measures the average volume of the individual erythrocyte. Under normal conditions, it is evidently equal to 1. Capps found that an increase in the volume index of the erythrocytes is one of the most constant and distinctive characteristics of pernicious anemia, which agrees with the well-known fact that many megalocytes are present in this disease, and that the color index is likewise greater than 1. [Capps' work is important in showing that the color index never exceeds the volume index in pernicious anemia; in other words, that the corpuscles are not supersaturated with hemoglobin. The volume index may be above the color index; it is apt to fall less rapidly from blood destruction and to return more rapidly to the normal during blood regeneration than the volume index. The high color index, therefore, depends upon the increased size of the cells. Capps found no evidence of an acute drop of the red cells.—Ed.] The secondary anemias, on the other hand, usually exhibit a diminished volume index of the erythrocytes. The same is true of chlorosis, in which affection a normal or slightly diminished volume index gives a good prognosis, while a markedly diminished volume index is less favorable. When utilized in this manner, the volume index is much more reliable for prognosis in chlorosis than is the hemoglobin percentage or the color index.

Capps also found that in normal erythrocytes with a volume index of 1, the discoplasm is saturated with hemoglobin, so that a color index greater than 1 indicates an enlargement of the erythrocytes. Upon the other hand, the color index may fall irrespective of a corresponding diminution of the volume index. It consequently follows that if the color index of the erythrocytes be above normal, the volume index must also be increased; while if the color index be below normal, the volume index is not necessarily diminished. The osmotic pressure of the blood-plasma should have no influence upon the volume index. The author finds this difficult to understand, and believes that it requires further investigation.

NUCLEATED RED CELLS (ERYTHROBLASTS) AND FREE NUCLEI; CABOT'S AND SCHLEIP'S RING FORMS

Nucleated red blood-corpuscles do not occur in normal blood. They may be considered as evidence of some abnormality in regeneration. They are found especially in anemic conditions. Ehrlich subdivides the nucleated red blood-cells into normoblasts and megaloblasts. The normoblasts are red blood-corpuscles about the size of normal cells, with one or sometimes several nuclei. These nuclei stain intensely with nuclear stains, such as hematoxylin, methylene-blue, Giemsa's, and Leishman's stain; and usually much more intensely than the nuclei of leukocytes or than any other nuclei. This staining quality is very characteristic, and enables us to recognize the free nuclei of normoblasts when found in the blood. Unstained, the nuclei of normoblasts appear as bright centers in the red blood-corpuscles, free from hemoglobin. They differ from the normal depression of red cells by their sharp outline, and from endoglobular degeneration in being somewhat granular (a normoblast is represented in Plate 8, Fig. 5, and in Pl. 4, Fig. 4 *b*; a free nucleus from a normoblast in Pl. 4, Fig. 4 *f*, and Pl. 5, Fig. 3, No. 29). We sometimes observe red corpuscles with two well-developed nuclei which sometimes exhibit mitoses. The nucleus of young normoblasts at times resembles the spokes of a wheel (Pappenheim). With increasing age the nucleus becomes thicker or denser (*pyknotic*), so that it is stained homogeneously and deeply. Megaloblasts are considerably larger than normoblasts—two to four times as large. The nucleus, although somewhat larger than that of a normoblast, occupies a comparatively smaller portion of the cell. It is less distinctly outlined, and does not have the same affinity for nuclear stains, so that

it is usually but very faintly stained. Staining brings out its net-like structure (see Pl. 5, Fig. 4 c), although the nucleus of an old megaloblast may be pyknotic, and when stained, appear very dark indeed. (See Pl. 4, Fig. 4 e.) Megaloblasts not infrequently show polychromatophilia. (See p. 784 and Pl. 4, Fig. 4 c, Pl. 5, Fig. 3, No. 26.) It is usually easy to differentiate well-marked normoblasts from megaloblasts, but many nucleated red blood-corpuscles are difficult to classify, and their classification depends to some extent upon the observer. (See Pl. 4, Fig. 4 e, and legend.) Most hematologists agree with Ehrlich that there is a distinct difference between normoblasts and megaloblasts, that the former represent the type of blood-formation in the adult, and the latter, the embryologic stage of blood-formation. The occurrence of transitional forms, however, is not thus precluded. It was formerly assumed that the fate of the nuclei in the two types varied, that the normoblasts became fully developed red blood-cells by extrusion of the nuclei, and the megaloblasts, by disintegration of the nuclei inside of the corpuscle. This opinion is, however, no longer held by modern hematologists. According to Nägeli, the destruction of the nuclei in the red cells by karyolysis (solution) and karyorrhexis (disintegration) must be considered physiologic (occurring in the bone-marrow); while the extrusion of normoblast nuclei into the plasma, which has been observed as well as inferred from the presence of free nuclei, is pathologic, if not artificial, because it takes place in the blood itself. Of clinical significance is the fact that normoblasts are observed in those anemic conditions in which the erythrocytes develop after the normal type of the adult organism. To this group belong cases of acute and chronic hemorrhages, and anemia following inanition, cachexia, blood-poisoning, hemoglobinemia, etc., i. e., in so-called secondary anemias and also in chlorosis. Normoblasts have also been found in the blood in tumors of the bone-marrow. Megaloblasts, on the contrary, seem to be the clinical indication of some severe degenerative change of the bone-marrow, which it is presumed is subjected to abnormal chemical (toxic) influences. They are frequently found in pernicious anemia. This occurrence makes the prognosis grave and unfavorable, except in the type of anemia which is due to the presence of the *Bothriocephalus*. In leukemia both normoblasts and megaloblasts are observed, the latter predominating.

C. S. Engel¹ has noted the transitory appearance of megaloblasts not infrequently in the blood of children, although no serious significance need be attached to the finding.

In secondary anemia large numbers of normoblasts may at times be found in the blood—the so-called “blood-crises” of v. Noorden. Megaloblastic blood-crises have not been observed.

In poikilocytosis, deformed blood-corpuscles with nuclei are sometimes found. (See Pl. 4, Fig. 4 d.) They are termed poikiloblasts, and according to their morphology may be normoblasts or megaloblasts. The poikiloblast pictured in Pl. 4, Fig. 4 d, belongs to the latter type.

Cabot's Ring-bodies in Anemic Blood.—Cabot, and later Schleip, have, independently of each other, demonstrated peculiar ring-shaped or loop-shaped structures inside the red cells, which, according to Schleip, represent nuclear remains. They are present in anemic blood, especially in pernicious and severe secondary anemia, leukemia and pseudoleukemia, and in lead-poisoning. They are very oddly shaped, and stain best with Giemsa's or Leishman's stain, which colors them red or violet. They occur in red cells which appear normal in other respects, as

¹ Deut. med. Woch., 1906, vol. xxix, p. 1165.

well as in association with polychromatophilia and basophilic degeneration, and sometimes together with other nuclear remains. They are pictured on Pl. 5, Figs. 30-35, after Schleip's drawings. These peculiar structures are apparently products of a regressive metamorphosis of erythrocyte nuclei, and, like nucleated red cells and basophilic degeneration, seem to have some connection with pathologic phenomena of blood regeneration, to which, indeed, the latter also give evidence.

VARIETIES OF LEUKOCYTES

The following varieties of white blood-corpuscles may be differentiated (Ehrlich and Lazarus):¹

I. LEUKOCYTES IN NORMAL BLOOD

(a) **Lymphocytes.**—These are derived from the lymph-glands, from other lymphadenoid tissues, and, according to more recent ideas, partly from the bone-marrow. They are, for the most part, small cells, usually about the size of red blood-corpuscles, often rather larger, with a large, centrally placed nucleus and a small margin of protoplasm. (See Pl. 4, Fig. 4, *h-l*, Pl. 5, Fig. 2, Nos. 10-13, and Pl. 6, Fig. 1, No. 7.) The nucleus stains rather intensely with nuclear stains, especially hematoxylin, somewhat less intensely with methylene-blue, and faintly with the triple stain. Between nucleus and protoplasm we can frequently see a narrow zone, either very faintly stained or without color. Ehrlich and Lazarus believe it to be due to an artificial retraction. In children especially and also in adults large lymphocytes are found as well as these small ones. These may be double the size of red blood-corpuscles, but are otherwise very much like the smaller ones in appearance (Pl. 4, Fig. 4, *n* and *m*, and Pl. 5, Fig. 2, Nos. 10 and 12).

They must not be confused with true so-called large lymphocytes or, better, lymphoid cells (p. 793, Pl. 4, Fig. 3, *c*, and Pl. 5, Fig. 3, Nos. 22 and 23), which are pathologic. The nuclei of the lymphocytes possess a coarse chromatin reticulum, and, after fixation at high temperatures, show one or two (never more) nucleoli, which have at times a deeply stained nucleolar membrane (Pl. 5, Fig. 2, No. 10). These nucleoli are most clearly recognized in smears stained with methylene-blue after fixation at high temperature, but are not detected in the ordinary Jenner and triacid preparations. In the protoplasm a basophilic reticulum can be demonstrated by staining with methylene-blue. This is best developed at the periphery, and is scanty near the nucleus (Pl. 4, Fig. 4, *i* and *m*, Pl. 5, Fig. 2, No. 2, and Pl. 6, Fig. 2, No. 7). Lymphocytes show no granulations with ordinary stains, but by using the azure dyes (Giemsa and Leishman stains), the so-called azure granules, of a red or violet tint, may be found in a minority of the cells (in one-third, according to Nägeli, Pl. 5, Fig. 2, No. 10). The nature and significance of these granules are not clear. They are usually considered products of the senile degeneration of the lymphocytes, and not true granulations, like those of other leukocytes. In lymphatic leukemia they are usually absent, but the author has found them even here.

In triacid preparations the nuclei of the lymphocytes appear pale bluish green, the protoplasm almost colorless or a pale pink (Pl. 6, Fig. 1, No. 7). Methylene-blue stains the nucleus more deeply or more faintly than the cell-body, depending on the degree of fixation. Pyronin

¹ Ehrlich and Lazarus, *Anemia*, in Nothnagel's System.

methyl-green stains the cell-body an intense red, the nucleus blue, and the nucleolus pink. Azure (Giemsa's and Leishman's stains) colors the protoplasm blue and the nucleus a deep violet.

Lymphocytes are fragile structures, and even slight pressure suffices to tear the protoplasm away either wholly or in part from the periphery, so that the cells assume a ragged contour (Pl. 4, Fig. 3, and Pl. 5, Fig. 2, No. 11).

They exhibit very slight active movements on the warm stage, and their migration from the blood-vessels cannot be regarded as proved. Lymphocytes contain neither autolytic ferments nor oxydases. They do not react to the guaiac test (lymphatic leukemia, see p. 856).

The normal number of lymphocytes is 22 to 25 per cent. of the total number of leukocytes, *i. e.*, 1500 to 1700 per cubic millimeter (up to 70 per cent. in children, according to Nägeli). During digestion the number of lymphocytes should probably increase *digestion lymphocytosis*.

According to Ehrlich and Pappenheim,¹ lymphocytes are also found in the bone-marrow; in fact, the latter believes that these lymphocytes of the bone-marrow are the progenitors of all the myeloid elements. Nägeli considers Pappenheim's belief to be erroneous. According to him, the lymphocytes are developed chiefly in the lymph-nodes, in the follicles of the spleen, and perhaps also in the small disseminated accumulations of lymphoid tissue in different organs, *e. g.*, the intestine. Nägeli calls the lymphocyte-resembling cells in the bone-marrow "myeloblasts," and, as opposed to other authorities, considers that lymphatic structures have not been demonstrated in the bone-marrow. (See p. 793.)

(b) **Large Mononuclear Leukocytes** (Pl. 4, Fig. 4, o, and Pl. 5, Fig. 2, Nos. 7-9, and Pl. 6, Fig. 1, Nos. 5 and 6).—These are cells two or three times as large as red blood-corpuscles, 12 to 20 μ in diameter, with large oval nuclei usually situated eccentrically and staining faintly (less intensely than the nuclei of lymphocytes). They are easily damaged in making the smears, and then exhibit irregular outlines. There is a little less distinct reticulum in the protoplasm than in that of the large lymphocytes, with which these cells are often confused. Granules are rarely seen when they are stained with methylene-blue, but though they were formerly considered free from granules, there are, according to Nägeli, in many specimens, at least in pathologic cases, scanty, fine neutrophile granules which may be demonstrated by using a good tri-acid stain. There is thus no distinct boundary between large mononuclears and transitionals. With Giemsa's and Leishman's stains azure granules may be demonstrated, and, according to Nägeli, the former imparts a dusky tint to the protoplasm, though not in all specimens. The position of large mononuclears in the classification of leukocytes is still very uncertain. Ehrlich's school regards them as quite immature elements of the bone-marrow at an earlier stage of development than the myelocytes. Pappenheim thinks they belong to the lymphocytes, while Nägeli considers them especially differentiated, mature elements of the myeloid group. They are frequently mistaken for large lymphocytes, but have more protoplasm and a nucleus which stains rather faintly. Their differentiation is sometimes, however, very difficult. It is perhaps easiest in pyronin methyl-green preparations, in which the cell-bodies of the lymphocytes are an intense red, and those of the mono-

¹ *Neuere Streitfragen aus dem Gebeite der Hämatologie*, Zeit. f. klin. Med., 1902, vol. xlvii, pp. 3 and 4.

nuclears a pale rose color. This stain, however, is not suitable for ordinary examinations, so that the author recommends the use of Jenner's solution after fixation at high temperature. In such preparations the lymphocytes are easily recognized, since in contrast to the large mononuclears their cell-bodies are darker blue than the nuclei. The normal percentage of this group is about 1 per cent. of the leukocytes, *i. e.*, 70 for each cubic millimeter.

(c) **Transitional Cells** (Pl. 4, Fig. 4, *p*, Pl. 5, Fig. 2, Nos. 5 and 6, and Pl. 6, Fig. 1, No. 4).—These are very much like (*b*), except that the nucleus is quite irregular in shape and stains more deeply and the protoplasm exhibits a less distinct reticulum and contains a few fine neutrophilic granules. They are regarded as derivatives of the marrow and ancestors of group (*d*). They occupy a position between the exclusively pathologic myelocytes and the polynuclears, and are actually immature forms of the latter. The number of transitional cells is normally from 2 to 4 per cent. of the leukocytes, *i. e.*, 140 to 280 per cubic millimeter. In counting they are usually included in one group with the related type (*b*). The normal number for the combined group (*b* and *c*) is about 3 to 5 per cent., *i. e.*, 210 to 350 per cubic millimeter.

(d) **Polynuclear** or, better, **polymorphonuclear neutrophilic leukocytes** (Pl. 4, Fig. 1, *h*, 2 *b*, 3 *b*, Pl. 5, Fig. 2, No. 1, and Pl. 6, Fig. 1, No. 1), are from 9 to 12 μ in size; they are characterized by a polymorphous, irregularly shaped or bent nucleus, which occupies only a small part of the cell, and which may be readily confounded with multiple nuclei. Indeed, acted upon by acetic acid, it may be separated into several nuclei, a change which also occurs probably when the leukocytes leave the vascular system and become pus-corpuscles (hence the incorrect name "polynuclear cells," which is almost impossible to eradicate). The nuclei stain very intensely, the chromatin is arranged in loops, the protoplasm is very densely packed with neutrophilic granules, and elsewhere oxyphilic; but in the young cells there is a faintly neutrophilic reticulum. No nucleoli are visible. Ehrlich's triacid solution stains the characteristic granulations most distinctly, imparting to them a violet color (Pl. 6, Fig. 1, No. 1). They are stained the same tint, but less surely, and more as a result of accident, by Jenner's (Pl. 4, Fig. 1, *h*, Fig. 2, *b*, and Fig. 3, *b*) and Giemsa's (Pl. 4, Fig. 2, No. 1) solutions. After decided fixation the eosin of these two stains imparts a deeper red tint to the neutrophile granulations. They may then be differentiated from coarser eosinophile granulations by their delicacy. The polynuclear neutrophiles arise exclusively from the bone-marrow, and in fresh preparations exhibit active ameboid movement. As true phagocytes, and by virtue of their fermentative properties (they contain oxydase and tryptic ferments), they play an important physiologic rôle. They are the essential constituents of pus, where, however, they lose many of their characteristics, especially, to a greater or less degree, the distinctive staining of their neutrophile granules and of their nuclei. The pathologic iodine reaction affects chiefly these cells. (See p. 781.) The normal number of polymorphonuclear cells is about 70 to 72 per cent. of the leukocytes, *i. e.*, 4900 to 5040 per cubic millimeter.

(e) **Eosinophilic Cells** (Pl. 4, Fig. 4, Fig. 2, *e*, Pl. 5, Fig. 2, No. 2, and Pl. 6, Fig. 1, No. 2).—These resemble the polymorphonuclear

PLATE 5.

Fig. 1

Fig. 3.

FIG. 1.—A case of myeloid leukemia. (Enlarged, 570 \times ; oil-immersion, $\frac{1}{2}$.) Jenner stain: a, Erythrocytes; b, neutrophile polynuclear leukocytes, some of them dwarf; c, neutrophile myelocytes, some of them dwarf; d, eosinophile myelocyte; e, mast-cells and mast-cell myelocytes; f, myeloblasts; g, lymphocytes; h, normoblasts.

FIG. 2.—Normal blood-corpuscles. (Oil-immersion, $\frac{1}{2}$; enlarged about 700.) Giemsa's stain: 1, Polynuclear neutrophile leukocyte; 2, polynuclear eosinophile leukocyte; 3, polynuclear mast-cell, some of the granules stained, some unstained; 4, mast-cell, with most of the granules unstained; 5, transition cell with violet protoplasm; 6, transition cell with blue plasma; 7, 8, 9, various forms of mononuclear cells; 10, 11, 12, 13, various normal lymphocytes; 14, erythrocytes.

FIG. 3.—Pathologic blood-cells. Giemsa's stain (same magnification): 15, Neutrophile myelocyte; 16, eosinophile myelocyte; 17, mast-cell, with deeply staining granules; 18, pathologic myeloid cell with both basophile and eosinophile granules; 19, 20, 21, Türk's irritation forms (so-called plasma cells); 22, pathologic lymphocytes (Rieder's forms), with indented nuclei; 23, pathologic lymphocytes with double nucleus; 24, myeloblast (after Nägeli); 25, normoblast; 26, polychromatophile megaloblast; 27, granular erythroblast with two nuclei; 28, polychromatophile erythrocyte; 29, free nucleus of a normoblast; 30-35, several Cabot-Schleip ring-forms (after Schleip); 36-39, malarial plasmodia; 36, usual form; 37, ring-form; 38, crescent; 39, mulberry body.

neutrophiles, except that the small neutrophilic granules are replaced by coarse oxyphilic granules. The triacid mixture stains the latter a red to an orange or a copper color. Jenner's and Giemsa's stains produce a pure eosin color. The coarse granules refract the light so strongly that these cells are readily recognized without staining. When unstained, however, they might be mistaken for mast-cells (see below), although the granules of the latter are usually much coarser. The eosinophiles normally furnish between 2 to 4 per cent. of the leukocytes, *i. e.*, 140 to 280 per cubic millimeter.

Eosinophilia (an increase in eosinophiles) is present in most cases of myelogenous leukemia, at the height of scarlet fever, in all forms of helminthiasis, in asthma, hay-fever, and many cases of emphysema, and in many skin diseases—pemphigus, urticaria, prurigo, eczema, and mercury dermatitis. (See p. 808.) Nägeli found eosinophilia frequently in neurasthenia and also in nervous diarrhea. It occurs during convalescence from most infectious diseases. On the other hand, the eosinophiles disappear in insufficiency of the bone-marrow, pernicious anemia, and at the height of all infectious diseases except scarlet fever. Eosinophiles are developed exclusively in the bone-marrow. The mononuclear eosinophiles present in the sputum of asthma and of the so-called eosinophile bronchitis are apparently degeneration forms of the polymorphonuclear eosinophiles of the blood.

(*f*) **Mast-cells** (Pl. 4, Fig. 2, *g*, Pl. 5, Fig. 2, Nos. 3 and 4, Pl. 6 Fig. 1, No. 3) are cells of the polymorphonuclear or transitional type, with marked basophilic granules, which are quite large, uneven, and irregularly distributed, and which usually are not much larger than the eosinophile granules. They are not distinctly stained by the triple stain, but are visible as little cavities in the protoplasm (negative staining, Pl. 6, Fig. 1, No. 3). They are, on the other hand, deeply stained with alcoholic methylene-blue or with Jenner's stain, and if the latter contain an azure dye, they are metachromatic, *i. e.*, violet instead of blue. Leishman's stain imparts a deep violet to black color to these basophilic granulations. Giemsa's solution stains only a part of them (Pl. 5, Fig. 2, Nos. 3 and 4). They arise exclusively from the bone-marrow. The number of these cells in normal blood is about 0.5 per cent. of the leukocytes, *i. e.*, 35 per cubic millimeter.

These figures for the proportions of the various kinds of leukocytes in the blood should be modified in the case of children below five years of age, where the mononuclear cells predominate. From the fifth year on, the polynuclear cells reach 50 per cent.¹ There is as yet no more accurate information regarding the occurrence of any individual type of leukocyte in children of different ages.

II. PATHOLOGIC LEUKOCYTES

(*a*) **Myelocytes.**—(*a*) **Neutrophilic Myelocytes** (*Mononuclear Neutrophiles; Marrow-cells; "Markzellen"* (Ehrlich), *improperly often designated as myelocytes without qualification*).—These cells are the immature progenitors of polynuclear neutrophiles, which normally remain in the bone-marrow. They are large cells with a large, faintly staining nucleus, differing from the large mononuclear cells of normal blood by the presence in the protoplasm of a much more profuse content of

¹ Besredka, Ann. Pasteur, 1898, No. 5, p. 327 et seq.

neutrophile granules, and by the diminished amount of the protoplasm (see Pl. 4, Fig. 2, *c* and *d*, Pl. 5, Fig. 1, *c*, Fig. 3, No. 15, and Pl. 6, Fig. 2, No. 9—mononuclear cells). They form the distinctive characteristic of the blood in *myelogenous leukemia*; but they may be found under other pathologic conditions; for instance, in *malignant tumors of the bone-marrow*, in *anæmia pseudoleukemica infantum* of v. Jaksch, and in leukocytoses. (See p. 804 et seq.) They are not found in normal blood, or if so, they are so scattered that they are not included among normal leukocytes. There is, as in most immature myeloid cells, a faint basophile reticulum. The cells vary in size. The nucleus is usually faintly stained, but may assume a deeper tint. Myelocytes play approximately the same rôle in the life of white blood-cells that erythroblasts do in the life of red cells.

(β) **Eosinophilic Myelocytes** (*Mononuclear Eosinophiles*, see Pl. 4, Fig. 2, *f*, Pl. 5, Fig. 3, No. 16, and Pl. 6, Fig. 2, No. 10).—Ehrlich and Lazarus consider them to be progenitors of normal eosinophilic cells, bearing the same relation to these cells as do the neutrophilic myelocytes to the neutrophilic polymorphonuclears. They occur, like the latter, especially in myelogenic leukemia. Very small cells of this type, which are not infrequently observed in leukemia, have been termed eosinophilic dwarf-cells.

(γ) **Basophile myelocytes** (*marrow mast-cell myelocytes*), analogous to the basophile leukocytes, resemble the other myelocytes (*a* and β) except that they show basophile granulations. They are, as a rule, small.

The presence of great numbers of all types of myelocytes in the blood (usually the neutrophile myelocyte, *a*) always points to a serious change in the bone-marrow. According to Ehrlich, their occurrence during leukocytosis indicates that immature elements have reached the blood from the bone-marrow through the influence of chemotaxis. It depends also in some measure on the insufficiency of the bone-marrow. The appearance of many such cells at the height of an infection (*e. g.*, in pneumonia and diphtheria) is of bad prognosis. (See pp. 800 and 805.) The presence of myelocytes is of great diagnostic importance in the metastases of malignant tumors in the bone-marrow.

(*b*) **Small Neutrophilic Pseudolymphocytes** (*Neutrophil Dwarf Leukocytes*; see Pl. 6, Fig. 3, *b*).—These are small mononuclear cells with a deeply staining nucleus and neutrophilic granules. They are very rare. The presence of the deeply stained nucleus differentiates them from the small myelocytes. Ehrlich and Lazarus believe that they result from the division of ordinary polynuclear cells.

(*c*) **Irritation forms** (Türk), recently called "*plasma cells*" (see Pl. 5, Fig. 3, Nos. 19, 20), are mononuclear cells which resemble the lymphocytes in their characteristics, but are sometimes larger and without granules. They contain a relatively large amount of protoplasm, so that the nucleus seems smaller than those of lymphocytes. It is round or oval, and frequently placed eccentrically. It is colored a dusky grayish brown by the triacid stain (according to Nägeli), and the protoplasm a deep reddish brown. Methylene-blue brings out the reticulated structure in the protoplasm, which is strongly basophile. Giemsa's and Leishman's solutions produce the same effect. The latter dye stains the nucleus a moderately deep violet, and the protoplasm a deep blue (Pl. 5, Fig. 3, Nos. 19–21).

PLATE 6.

Fig 1.

Fig 2.

Fig. 3.

FIG. 1.—Normal blood-corpuscles (triacid stain); $\times 700$: 1, Polynuclear neutrophile leukocyte; 2, polynuclear eosinophile leukocyte; 3, neutrophilic myelocyte; 4, transitional cell; 5 and 6, large mononuclear leukocyte; 7, lymphocyte; 8, erythrocyte.

FIG. 2. Pathologic blood-corpuscles (triacid stain), $\times 700$: 9, Neutrophile myelocyte, 10, eosinophile myelocyte; 11, normoblast; 12, megaloblast; 13, polychromatophilic erythrocyte; 14, three myeloblasts (after Nägeli).

FIG. 3 —Exudate from tuberculous pleurisy (Jenner's stain): *a*, Erythrocytes; *b*, neutrophile dwarf leukocytes; *c*, lymphocytes, *d*, endothelial cells of the pleura; *e*, endothelial masses, with neutrophile leukocytes enclosed or attached, *f*, endothelial cell containing a binuclear normoblast.

With pyronin methyl-green the cell-body appears a beautiful red, the nucleus a dusky grayish blue to violet, in contrast to the pale-blue nuclei of the lymphocytes. The nuclei often show mitotic figures. These cells are found in certain (lymphatic) leukemias and, according to Nägeli, even in leukocytosis and severe anemia. Türk found them under the same conditions with the myelocytes as a product of the irritation of the bone-marrow, hence the name, *irritation forms*. Nägeli formerly regarded them as myeloid forms without granulations and as only pathologic; while Schleip considers them descendants of the lymphocytes, an opinion in which Nägeli seems recently to have concurred, at least so far as their appearance in leukemia is concerned.

(d) Pathologic Large Lymphoid Cells.—In this class belong, first of all, the lymphocytes of leukemic and pseudoleukemic blood, which, on account of their size, are often called briefly large lymphocytes, a name not quite suitable, since there are also small types and since even the large forms are essentially different from the normal large lymphocytes mentioned on p. 788. It is perhaps more fitting, in order to clear up this confusion, to call them large pathologic lymphoid cells. (See Pl. 4, Fig. 3.) They have the general characteristics of normal lymphocytes, but differ from the latter in their size, which is frequently twice as great, and their defective staining qualities, which may be demonstrated with the triacid as well as with Jenner's solution. This is true of the nucleus as well as of the cell-body. They stain better by Giemsa's, Leishman's, and the eosin-hematoxylin methods. But even then the protoplasm is pale and the nucleus poor in chromatin. One or two nucleoli are present in the latter. The nuclei often show peculiar changes (indentations and fractures), described by Rieder¹ and by Ehrlich and Lazarus.² (See Pl. 5, Fig. 3, Nos. 22 and 23 and Schleip's³ excellent plates.) The practiced observer will not confuse these forms with the broken nuclei of the polynuclear cells. Azure granules are seen only very rarely in these lymphoid cells.

Nägeli considers these pathologic, usually large, lymphoid cells the ancestors of ordinary lymphocytes, and assumes that they are formed in the germinal centers of the lymph-nodes and in the follicles of the spleen, since they correspond to the cells in those places. They appear in the blood in all cases of lymphatic leukemia, especially in the acute forms, and, furthermore, in lymphomatosis and lymphocytosis, *e. g.*, in typhoid fever (Nägeli).

Besides these pathologic large lymphocytes, there occur, in analogous conditions, smaller cells (the size of the ordinary lymphocytes) which differ from the latter chiefly in their paucity of chromatin.

(e) Myeloblasts (Nägeli).—By this term Nägeli designates marrow-cells without granulations, which reach the blood-stream in severe diseases of the bone-marrow and are the ancestors of the myelocytes. Formerly, and to some extent even now, they were classed by many writers as lymphocytes. They are found especially in myeloid leukemia, a strong argument in favor of their myeloid character. Nägeli has shown that they differ from large pathologic lymphoid cells (*d*), with which they were until now confused, principally by the capacity of their nuclei to take up the triacid stain. In contrast to the pale nuclei of the cells of group

¹ Rieder, *Atlas der klin. Hämatologie*, 1893.

² *The Anemias in Nothnagel's System*, 1905.

³ Schleip, *Atlas der Blutkrankheiten*, Urban und Schwarzenberg, 1907, Fig. 47.

(d) the nuclei of myeloblasts become a dusky grayish blue, while the protoplasm appears rose colored (Pl. 6, Fig. 2, No. 14). With methylene-blue, and also with Giemsa's and Leishman's stains, the protoplasm is seen to be rather decidedly basophilic (Pl. 5, Fig. 3, No. 24). Even in myeloblasts stained with methylene-blue after strong fixation by heat the nuclei are paler than the protoplasm, and the nucleoli, in contrast to those of lymphocytes, are barely visible and number 2 to 4 (usually 3 or 4). One can best convince himself of the numerous nucleoli by the use of Giemsa's stain, which colors them a distinct blue, distinguishing them from the pink nucleus (Pl. 5, Fig. 3, No. 24). With pyronin methyl-green the nucleoli appear to be pale pink or almost colorless, round structures in a blue nucleus. In contradistinction to normal lymphocytes no azure granules are present. Nägeli considers that the presence, in myelogenous leukemia, of numerous intermediate forms, from myeloblasts to cells with neutrophile granulations, particularly favors the supposition that these structures belong to the myeloid system. The author confirms this finding and its occurrence also in the bone-marrow. Nägeli lays down the following rules for the differentiation of myeloblasts from other cells.

"Myeloblasts differ—(1) from large mononuclears by their round or oval nucleus, rich in chromatin; (2) from pathologic large lymphoid cells by the better staining nucleus, richer in chromatin, and containing more nucleoli, which are not clearly stained by methylene-blue; (3) from older, larger, normal lymphocytes (such as are found in children, p. 788), by their darker nucleus, strongly basophilic protoplasm, and the absence of azure granulations."

According to Nägeli, myeloblasts are found in pernicious anemia and in the anemias of children, as well as in myeloid leukemia.

DIFFERENTIAL COUNTING OF LEUKOCYTES AND THEIR PROPORTIONS UNDER NORMAL CONDITIONS

If it be desired to differentiate simply the mononuclear and polynuclear elements, the differential count may be made in the ordinary counting chamber from blood treated with dilute acetic acid, which renders the nuclei quite distinct. For the further differentiation of the several varieties of leukocytes (see p. 776), dry specimens stained with eosin hematoxylin may be employed. These preparations, however, suffice to establish merely the gross relations, *e. g.*, to differentiate and form a judgment of the severity of lymphatic and myeloid leukemia or to recognize eosinophilia. For examination and a complete differential count of all the varieties of the white cells we must employ other methods, *e. g.*, Ehrlich's triacid mixture, Jenner's, Giemsa's, or Leishman's solutions. (See p. 777 et seq.) If the white cells be only moderate in number, the visual field of the microscope may be employed as the unit of space for their enumeration. By tabulating the numbers of each variety of leukocytes seen in a large number of fields it is easy to calculate their relative percentage. With the help of a movable stage the entire preparation may be counted exactly. If, however, the number of white cells be materially increased, this process is very tedious. Ehrlich, therefore, devised and had Leitz manufacture a peculiar ocular, fitted with a simple removable screen, by means of which quadrilateral fields of any size desired may be secured. The size of the fields is selected to conform to the number of the corpuscles in the preparation. With this help both the total count and the differential

count of the different varieties of leukocytes can be very easily made; and sufficiently large absolute counts can be made by merely sliding the preparation to and fro. It is the most convenient and least tedious method of counting. Ehrlich employs it in determining the relative number of red and white cells; but for this purpose it is more convenient to compare the absolute numbers of red and white cells with each other, since otherwise their relative proportions possess neither physiologic nor diagnostic interest.

Whichever of the above-mentioned methods we may employ for the differential counting of the separate varieties of leukocytes, it is always advisable to control these relative counts by the absolute count of the leukocytes obtained in the usual way (see p. 757), and expressed in terms of the cubic millimeter of blood. This enables us to construct graphic curves,¹ which are very helpful in considering the changes in the blood-picture.

Our knowledge of leukocytosis was at first considerably restricted by the fact that attention was drawn exclusively to the determination of the quantitative relation between the white and the red corpuscles. Similarly, the limitation of the investigation to the determination of the quantitative relations of the various leukocytes, without due regard to the absolute number of these cells, has also considerably restricted our knowledge of this topic. The whole study of leukemia and pseudo-leukemia suffers from this practice, which still obtains, of expressing the results of the differential count as mere percentages. Our knowledge of these diseases will be advanced much further if we always estimate the absolute number of each type of cell per cubic millimeter, since, of course, an absolute increase or decrease of a particular kind of leukocyte warrants the conclusion of an irritative or depressive disturbance of function of the tissue in which it develops; while such a conclusion is impossible from the differential count alone.

DIRECT DIFFERENTIAL COUNTING OF STAINED BLOOD IN THE COUNTING-CHAMBER

*Zollikofer's*² method of staining fresh blood-preparations in the counting-chamber, and then determining the absolute number of the different kinds of leukocytes present, is a welcome simplification.

The two following solutions are required:

I	
Eosin, w. g. (Grübler).....	0.05
Formalin, conc. (40 per cent.).....	1.00
Aquæ destillatæ.....	100.00
	Filter.
II	
Methylene-blue, B. X. (Grübler).....	0.05
Formalin, conc.....	1.00
Aquæ destillatæ.....	100.00
	Filter.

Both solutions are kept in dark bottles, and before using are mixed in about equal quantities with a medicine-dropper.

The blood is drawn into a Thoma-Zeiss leukocyte counter, and diluted 20 times with the freshly mixed stain. The stain after being mixed must be used

¹ Die Leukocytose beim Typhus abdominalis, Deut. Arch. f. klin. Med., 1903, vol. lxvii.

² Zeit. f. mik. Technik, 1901.

immediately, because a precipitate is formed if it stand for any length of time. The dilution of the blood with the stain must be done very rapidly, for if the blood remain in the capillary tube for any length of time, the red blood-corpuscles become visible.

The pipet is shaken for about five minutes, and a drop then placed on the counting-slide. The red blood-corpuscles, unless nucleated, are invisible. The leukocytes are preserved, and the individual kinds can be distinguished. The α (eosinophile) granules are stained yellowish to carmin, and are characterized by their size. The ϵ (neutrophile) granules are grayish violet, often filling up the entire body of the leukocyte, but in rare cases scattered only in the protoplasm. The γ (basophile) granules remain unstained. The leukocytes without granulations may be distinguished by the relative amount of protoplasm and the size of the nucleus, as lymphocytes or large mononuclear cells. The nucleus is less distinctly stained in the granular types, and for this reason the mononuclear granulated leukocytes (myelocytes) cannot be accurately separated from the polynuclear. The blood-platelets are of a bluish-violet tinge, and may be recognized by their typical grape-like arrangement. The proportion of the eosin to the methylene-blue can be so regulated that neither the nuclei nor the granules predominate.

The same mixture can be used in dry preparations which have been well fixed at 120° C. They should be stained for from one-half to one minute. Besides differentiating the various kinds of leukocytes, it stains malarial parasites, bacteria, and the basophilic granules of the erythrocytes, and shows the polychromatophilic changes of the red-cell plasma.

W. Türk makes use of the following diluting fluids: glacial acetic acid, 3 cc.; aqua dest., 300 cc.; 1 per cent. aqueous gentian-violet solution, 2 to 3 cc.; and he claims that the clear nuclear staining resulting therefrom is in most cases sufficient to differentiate the leukocytes. The eosinophile cells, of course, cannot be recognized because their granules are dissolved. The mast-cells, since their granules run together, are stained a uniformly dark violet, and after some practice will not be confused with other structures. Only in myeloid leukemia are some of the mast-cells not sufficiently characteristic. Even normoblasts may be recognized in these preparations, and, less surely, megaloblasts. Polychromatophilia may be recognized in that the discoplasm, which is otherwise hardly visible, appears pale blue. Türk believes that the use of this fluid simplifies the differential count in cases where it is not necessary to determine details not recognizable in such a preparation.

LEUKOCYTOSIS AND LEUKOPENIA

By the term *leukocytosis* is understood the state of the blood, occurring under various conditions, in which there is an increase of the white corpuscles, except where such an increase is due to the specific or idiopathic disease of the blood, leukemia. Most leukocytoses are characterized, in contradistinction to leukemia, by an increase in the polynuclear neutrophiles, which are derived from the bone-marrow, so that the term leukocytosis, used without qualification, usually means the increase of this kind of cell.

An unusual form of leukocytosis, except when it is associated with leukemia, is characterized by an increase in the number of lymphocytes—the so-called *lymphocytosis*.

Leukopenia is the reverse of leukocytosis, i. e., a diminution in the number of leukocytes.

Leukocytoses are either physiologic or pathologic. The polynuclear elements of pathologic leukocytoses are usually neutrophilic, so that a polynuclear neutrophilic leukocytosis is, as a rule, pathologic. There is, however, a pathologic eosinophilic polynuclear leukocytosis. These pathologic leukocytoses are explained by the presence of chemotactic substances in the blood-plasma, most of which exert a positive influence on the neutrophilic, and but little on the eosinophilic, cells. A leukocytosis in which the third kind of granular cells, the mast-cells, are increased is not as yet known. In leukemia, however, these cells are usually very much increased; and perhaps in this disease there is some

little positive chemotactic influence from the blood upon the mast-cells.

Immature forms from the bone-marrow, especially myelocytes (see p. 791), reach the blood in most polynuclear leukocytoses. If abundant, they are evidence of a certain functional insufficiency of the bone-marrow. (See p. 791.)

PHYSIOLOGIC LEUKOCYTOSES

To this group belong the leukocytosis of digestion, the leukocytosis after exertion and after a cold bath, the leukocytosis of pregnancy and that of the new-born.

The *leukocytosis of digestion* begins about one hour after a meal, and reaches its maximum (a 30 to 40 per cent. increase of the white cells) in about three to four hours (Rieder). It is most marked after food rich in proteids. Considering the comparatively slight digestion leukocytosis, any great degree of pathologic leukocytosis can be recognized even during digestion. According to Rieder, both mononuclear and polynuclear cells are increased so that their relative percentage is unchanged. The eosinophiles, on the contrary, are much diminished.

Very little definite information is as yet at hand regarding the *leukocytosis after exertion and cold baths*. It is not yet known whether there is an actual increase in the total number of leukocytes, or whether this is only a pseudoleukocytosis, *i. e.*, one produced by an accumulation of leukocytes in the skin vessels. The *leukocytosis of pregnancy* may amount to 50 or 80 per cent., is present only in the later months of pregnancy, and disappears rapidly after delivery. The relative percentages of all varieties including the eosinophiles remain normal (Rieder).

Leukocytosis of the New-born.—The white count is two or three times the normal during the first day of life. It then diminishes to normal, and increases again after the first week, remaining for several weeks at about 50 per cent. above the normal. Rieder found in this leukocytosis a preponderance of the mononuclears. (See Lymphocytes, p. 789.) He also found that the blood of the new-born contained a high percentage of eosinophiles and normoblasts, and exhibited a moderate poikilocytosis.

THE BLOOD IN THE INFECTIOUS DISEASES; INFECTIOUS LEUKOCYTOSIS AND LEUKOPENIA¹

Most infections cause a leukocytosis (polynuclear neutrophilia) probably through the influence of the toxins excited by the disease and produced in the body. This is generally understood to be a defensive reaction of the bone-marrow. In only a few infectious diseases is there a leukopenia.

K. Ziegler² found that, following the recession of the polynuclear leukocytosis, there regularly occurs a secondary and usually a transitory and brief increase in the large mononuclears. The lymphocytes next begin to increase above normal, while the neutrophile curve sinks still lower, so that the greatest increase in the lymphocytes often occurs at the same time when the neutrophiles are least. Ziegler calls this time the crisis of blood regeneration. From this point on the white cells begin to approach the normal. Toward the end of the lymphocytosis Ziegler usually found an increase in eosinophiles and mast-cells.

¹ Chiefly compiled from Rieder, *Beiträge zur Kenntnis der Leukocytose*, Leipzig, Vogel, 1892; Türk, *Klinische Untersuchungen über das Verhalten des Blutes bei acuten Infektionskrankheiten*, Wien und Leipzig, 1898; O. Nägeli, *Ueber die Typhus-epidemie in Oberbipp, ein Beitrag zur Aetiologie und Hämatologie des Typhus abdominalis*, *Correspondenzbl. f. Schweizer Aerzte*, 1899, No. 18; and *ibid.*, *Die Leukocyten beim Typhus abdominalis*, *Deut. Arch. f. klin. Med.*, 1900, vol. lxxvii, p. 279; Schindler, *Zeit. f. klin. Med.*, 1904, vol. liv; Arneth, *Die neutrophilen weissen Blutkörperchen bei Infektionskrankheiten*, Jena, Fischer, 1904; Nägeli, *Blutkrankheiten und Blutdiagnostik*, Leipzig, Veit, 1908; and Ziegler, *Arch. f. klin. Med.*, 1908, vol. xciv.

² *Arch. f. klin. Med.*, 1908, vol. xcii.

These observations evidently imply a general formula for the typical relations demonstrated by Nägeli in typhoid fever as well as a general conformity to law whose physiologic meaning is not yet fully clear.

Ziegler, however, emphasizes the extreme variations of detail in the blood changes in different infections and different individuals affected by the same disease, so that it is difficult or impossible to construct such characteristic curves as Nägeli has done in typhoid fever. (See p. 798 et seq.) The duration of the blood reaction is also very variable. Thus in most cases of pneumonia, erysipelas, and perityphlitis, and in some cases of diphtheria and scarlet fever, the blood-picture becomes normal in four to six weeks, while in others this occurs only after six to ten weeks.

Ziegler's observations should be classed with those of Schindler on the regularity of the occurrence of myelocytes in infectious diseases, and with Arneth's studies on the "neutrophile blood-picture." (See p. 805 et seq.)

Infectious Oligochromemia.—An interesting and noteworthy phenomenon to which Hayem in particular has called attention is the reduction of hemoglobin and the red-cell count in most infectious diseases. There are apparently several causes for this: (1) An increased destruction of the red cells because of their susceptibility to the toxins and because of the increased metabolism in fever; (2) a toxic interference with their production; (3) a thinning of the blood through the febrile retention of water. The last is certainly not the only cause, since the red cell and the hemoglobin content would be equally affected by water retention, and, according to Nägeli, the hemoglobin quotient or color index is generally less than 1. The degree of oligochromemia generally varies with the severity of the infection. Whether its presence permits merely of judging the condition of the patient at a given time or whether it has prognostic value has not yet been decided. Irregular staining of the red cells, polychromatophilia, and basophilic degeneration as well as normoblasts and megaloblasts have also been demonstrated in the most varied infections. It would seem worth while to investigate these phenomena more closely by means of extended and systematic studies after the manner of the writers who have of late years paid almost exclusive attention to the study of the behavior of the white cells. For it is clear that outside of their physiologic importance in overcoming disease, the red cells, as well as the leukocytes, could furnish us with conclusions as to the condition of that powerful defensive organ, the bone-marrow.

THE BLOOD-PICTURE IN INDIVIDUAL INFECTIOUS DISEASES

Pneumonia

Pneumonia is usually accompanied by a pronounced leukocytosis. The degree does not correspond to the severity of the infection, nor does it permit of an absolute prognostic conclusion. The leukocytes, as a rule, run from 15,000 to 30,000 per cubic millimeter. A drop in their number usually begins on the day of the crisis, or sometimes on the day before. It is not, however, common to have the number drop below the normal after the crisis. The leukocytosis of pneumonia is composed of neutrophils, the eosinophiles disappearing during the course of the disease. The reappearance of eosinophiles indicates that the height of infection has been passed, and is, therefore, suggestive of a favorable prognosis. It usually takes place on the day of the crisis, but sometimes one or two days before. Later the eosinophiles may be increased beyond the normal limits. A high normal leukocyte count with only a relative increase of the polynuclear neutrophils indicates a severe infection and reduced resistance, although from it a bad prognosis should not be given. Leukopenia in pneumonia suggests a dubious prognosis, although it does not necessarily indicate a fatal termination.

Typhoid

In striking contrast to pneumonia typhoid is usually characterized by leukopenia. Nägeli, continuing Rieder's and Türk's investigations, studied the hematology of typhoid more minutely. He has arrived at the following conclusions:

In the first stage (ascending fever curve) there is probably a moderate neutrophile leukocytosis. This may be inferred from the condition found in relapses. It soon diminishes, and is then followed by a diminution in the neutrophiles. The eosinophiles disappear entirely or very nearly. The diminution of lymphocytes is moderate.

In the second stage (fastigium, continued fever) the number of neutrophiles and lymphocytes diminishes still further, although the latter may be somewhat increased toward the end of this period.

In the third stage (period of remissions) the lymphocytes are frequently increased, and sometimes decidedly so. The neutrophiles are still more diminished, and the eosinophiles begin to reappear at the end of this period. In adults the lymphocytes may remain few in number.

The fourth stage (descending fever curve) is characterized by a still further diminution of the neutrophiles, which reach their minimum during this period. The lymphocytes are considerably increased, and may be much more numerous than the neutrophiles (crossing of the two curves). The eosinophiles begin to increase slowly and regularly.

In the first days after the fever disappears the neutrophiles begin to increase. The lymphocytes are very abundant and the eosinophiles continue to increase. Some time after the disease has run its course there may be a considerable lymphocytosis, a marked increase of eosinophiles, and normal or slightly increased numbers of neutrophiles. This condition is most pronounced in young individuals, especially two or three months after defervescence. In adults it is less marked, and usually disappears within two months; but in children it persists considerably longer.

During the active stage of the disease the variations in the leukocytes are more pronounced in children than in adults, especially the lymphocytes. On the other hand, even if children are extremely ill, the number of leukocytes is rarely as low as in adults (apparently due to a less severe involvement of the bone-marrow and the lymphatic apparatus).

Non-typhoidal complications, of course, influence merely the number of neutrophiles. They are usually increased, but generally not excessively, by suppuration, cystitis, parotitis, pleuritis, bronchopneumonia, nephritis, etc. Absence of leukocytosis in spite of complications indicates an insufficiency in the function of the bone-marrow. This is a dangerous condition (impossibility of forming new neutrophiles).

The blood-findings (lymphocytosis) may persist long after the disease has disappeared; they are very characteristic, and, as Nägeli has shown, may prove that a patient has ambulatory typhoid, although he is apparently well, often with even greater certainty than is possible with Widal's reaction, a fact which may be of considerable importance in determining the beginning of an epidemic of typhoid, and which was used by Nägeli in the epidemic at Oberlipp.

Diagnosis.—Nägeli emphasizes the following statement as a law: "A disease in which eosinophiles are present in one-half normal, normal, or increased numbers cannot be typhoid; and the appearance of even a few of these cells must incite caution in the diagnosis." The converse of this law he considers untrustworthy. A persistent leukocytosis also argues strongly against typhoid. In regard to the differential diagnosis, Nägeli insists that in other forms of *enteritis* leukocytosis almost always occurs; in *tuberculous meningitis* there is no leukopenia; in *general miliary tuberculosis* leukopenia is absent in the early stages and seldom occurs at all; and in *chronic tuberculosis* the eosinophiles are either normal or increased in numbers. *Paratyphoid* behaves, according to Nägeli, the same as ordinary typhoid.

Prognosis.—Nägeli considers favorable—(1) A slight-degree of leukopenia; (2) an incomplete disappearance of eosinophiles at the height of the disease; and (3) an increase in eosinophiles and lymphocytes in the third stage, indicating that the organism has begun to conquer the infection. In the presence of complications a marked leukopenia or even the absence of leukocytosis is of unfavorable import. Nägeli found that the blood-picture is not essentially altered after the administration of drugs or during digestion.

The cause of this most characteristic and interesting behavior of the blood in typhoid fever is, according to Nägeli's and Studer's experimental investigations, the pernicious influence of the typhoid toxins on the bone-marrow.

To complete this typhoid blood-picture, the diminution of fibrin, a fact first demonstrated by Hayem, should be noted. (See p. 771.)

The enumeration of the platelets in typhoid blood, by the new methods which permit of their absolute identification (see p. 809 et seq.), has not, to the author's knowledge, been attempted. Hayem¹ found, however, a diminution (to as low as

¹ Du Sang, etc., Paris, Masson, 1889.

60,000) in his so-called "hematoblasts," which doubtless nearly correspond to the platelets. The author strongly recommends estimating the number of blood platelets from fresh preparations, since, with a little practice, this may be done without actual counting. According to the experience in his clinic, the blood-picture in typhoid set forth above is quite as important in the diagnosis of doubtful cases as is the serum reaction, especially when the latter is negative.

Typhus Fever

According to the few observations extant,¹ typhus fever is apparently accompanied by a neutrophile leukocytosis.

Acute Articular Rheumatism

In uncomplicated cases of this disease there is usually a slight polynuclear neutrophilic leukocytosis (rarely above 15,000), which persists so long as there is fever and exudation (Cabot and Türk). The leukocytosis increases if complications occur (pleuritis, pericarditis). Eosinophiles are absent only in the very early cases, before there has been any amelioration of the symptoms. Later, usually before the termination of the illness, they reappear. The presence of eosinophiles is of favorable prognostic importance in this disease also.

Diphtheria

Neutrophile leukocytosis is usually present in this disease. The eosinophiles seldom disappear completely. According to K. Ziegler, lymphocytosis and an increase in the eosinophiles follow the recession of the leukocytosis. In a particularly severe fatal case Schindler observed the presence of numerous myelocytes (see p. 805), and he is inclined to confirm C. S. Engel's statement that the presence of large numbers of these cells is of bad prognosis.

Meningitis

In epidemic cerebrospinal meningitis there is always a pronounced polynuclear neutrophilic leukocytosis of varying degree, usually with a diminution in, sometimes with disappearance of, eosinophiles; but the latter increase in numbers with temporary or permanent improvement. According to the experience in the author's clinic, the behavior of these cells is quite as suggestive as in typhoid fever. In tuberculous meningitis the leukocyte count may be normal or distinctly increased (up to 20,000 and more). Absence of leukocytosis, then, points toward tuberculous meningitis, but its presence does not exclude this disease.

Septicemia and Malignant Endocarditis

In this disease there is usually a considerable polynuclear neutrophilic leukocytosis, with diminution in the lymphocytes and eosinophiles. Sometimes myelocytes and normoblasts are found. The platelets are usually increased. Only the most severe cases are unaccompanied by leukocytosis or even exhibit leukopenia. Türk emphasizes the presence of normoblasts in sepsis as a factor in excluding typhoid, but, according to Nägeli, this is not decisive. The marked reduction in hemoglobin and the occurrence of hemolysis and hemoglobinuria, particularly in streptococcus septicemia, should be noted. (See p. 719 et seq.)

Erysipelas

In the majority of the cases there is a moderate degree of polynuclear neutrophilic leukocytosis; in the minority the leukocyte count may be normal or only slightly increased. The degree of leukocytosis is of no prognostic value, except that, when marked, it suggests the formation of pus [or pneumonia.—Ed.] The eosinophiles are diminished in number or absent at the height of this disease also.

Scarlet Fever

Here, too, there is an increase of polynuclear neutrophiles. The characteristic feature of the leukocytosis of this disease is its persistence, for it does not disap-

¹ Nägeli, Blutkrankheiten und Blutdiagnostik, Leipzig, Veit, 1908.

pear for several weeks after the rash and the fever have vanished, a fact which can be made use of for diagnosis after the disease has run its course. In the very beginning of the disease the lymphocytes are very much diminished. The eosinophiles are somewhat diminished as soon as the rash appears; but while it persists, and during the period of desquamation, they may be normal, or at times very decidedly increased. The persistence of leukocytosis after this disease has run its course may possibly have some prognostic value in regard to the danger of late nephritis. In mild cases it is also frequently associated, according to the author's experience, with the slight, often disregarded, rise in temperature of some tenths of a degree over 37°C . (98.6°F .), which persists for about a week, but is not a true relapse. This temperature rise is barely referred to in the literature. According to Neutra,¹ the iodine reaction of the leukocytes is constant in the first days of the disease, and especially marked in severe cases. Kotschetkoff found a pronounced eosinophilia in fatal cases, and Nägeli is of the opinion that it depends on the development of the rash and is absent in the absence of the latter.

Measles

According to Renaud and Lagriffoul, leukocytosis occurs only in the period of incubation and during the prodromal stage of measles, and disappears with the onset of manifest symptoms. In uncomplicated cases it is replaced by a leukopenia similar to that in typhoid. This is most noticeable during the period of eruption, and especially when the latter is at its height, and gradually recedes during desquamation. The ratio between the polynuclear cells and the lymphocytes remains undisturbed. After the rash has disappeared, the total number of leukocytes increases to the normal, and the actual number of large mononuclear cells may be above the normal. The eosinophiles in the beginning of the incubation period are increased in number (Renaud). With the onset of manifest symptoms, up to the height of the disease, they are either normal or diminished, but subsequently they become slightly increased. A subnormal or a persisting normal number of leukocytes may be useful in the differential diagnosis between measles and scarlet fever. A marked eosinophilia and leukocytosis would be in favor of scarlet fever as against measles.

Rubella

In contradistinction to measles there is in the incubation and prodromal periods of rubella a distinct hyperleukocytosis, which persists to a less marked degree during the eruptive stage (Lagriffoul, Soc. de biol., Oct. 13-27, 1906).

Small-pox (Variola and Varioloid)

In variola Brouardel found a leukocytosis which reached its maximum on about the sixth day. Recent researches have revealed the same condition even in the prodromal stage. It is marked during vesiculation and especially so during pustulation, when the white cells may number 40,000. Lymphocytes are few, but numerous, large, often exceptionally large, mononuclears are present. According to Courmont and Montagard, the latter may reach 40 to 50 per cent. of the white cells, so that throughout the disease a distinct "mononucleosis" is present, a fact of great weight in the diagnosis. Myelocytes and normoblasts, as well as Türk's irritation forms, may be numerous at the beginning of pustulation. The persistence of eosinophiles is noteworthy. Nägeli draws attention to the fact that even in normal children numerous mononuclear cells are present and, therefore, emphasizes the diagnostic importance of the occurrence of numerous myelocytes and normoblasts.

In the modified form of variola known as *varioloid* the findings are, on the whole, the same as in severe variola (Courmont and Montagard).

According to Courmont, the morphologic blood-examination is of very great importance, for it enabled him to reach a diagnosis in all doubtful cases even in the early stages.

Varicella

In this disease Erben found a normal percentage of eosinophiles and an increase of the mononuclear leukocytes in a normal white count.

Influenza

On account of the vague conceptions of this disease, the author desists from quoting the data in the literature on the blood-findings.

¹ Zeit. f. Heilk., 1906, No. 11.

Dengue Fever.

According to Stitt,¹ the blood-picture in dengue is so characteristic that many cases in which the other clinical phenomena are not diagnostic may be recognized by the behavior of the blood. One finds a low percentage of polynuclears (40 per cent.), first a high (40 per cent.), then a low (10 per cent.), percentage of lymphocytes, and on the third or fourth day an increase of the large lymphocytes to 30 per cent., and of the large mononuclears to 40 per cent. Thus the curves of the small lymphocytes and the large mononuclears intersect. There are no data as to the absolute numbers.

Pertussis

Pertussis leads to an increase of the lymphocytes, and, to a less marked degree, also to an increase of the polynuclear leukocytes.

[Barach² found a typical blood-picture in this disease. At the onset there is a leukocytosis averaging 17,000 to 18,000, with increase of all the forms; then a small-cell lymphocytosis (51 per cent.) and a less marked increase in the number of large lymphocytes. Bilobed small lymphocytes and degenerated large mononuclears are frequently seen. Later there is a gradual decrease in the leukocytosis and a return to the normal differential count, except for a slight eosinophilia (5 per cent.), which may persist for months.—ED.]

Mumps

In mumps, even with high fever, F. Pick³ found no leukocytosis. He regards this of importance in the differential diagnosis of orchitis due to mumps from that due to gonorrhea, and concludes from it that the former is purely a serous inflammation. This, however, does not always seem to be the case, since other writers have found quite a high leukocytosis in mumps, as well as in mumps complicated by orchitis, evidently depending on the virulence of the disease.

Malta Fever

The few examinations extant in this disease reveal a normal number of leukocytes or a leukopenia.

Relapsing Fever

This disease gives rise to a marked neutrophile leukocytosis.

Tetanus

Very few data on the blood in tetanus exist. Apparently a moderate degree of leukocytosis occurs, but this is inconstant. (It may vary with the kind of infection.)

Rabies

Courmont and Lésieur found a neutrophile leukocytosis in this disease.

Anthrax

Anthrax causes a leukocytosis.

Cholera

The supposedly invariable concentration of the blood in this disease does not seem to be constant.⁴ A high degree of leukocytosis (up to 60,000) may be present.⁵

Malaria

According to Türk, the ordinary benign cases of malaria regularly show a leukopenia both during the paroxysms and in the intervals. During the paroxysm the

⁵ Biernack, Deut. med. Woch., 1895, p. 795, and Rogers, Lancet, 1902, p. 659.

percentage of neutrophiles is relatively increased at the expense of the lymphocytes and eosinophiles. Schindler has reached different conclusions. He observed a diminution of the leukocytes and an increase of the mononuclear cells between the paroxysms, with a reappearance of the normal figures at the height of the fever. Türk has counted the plasmodia as well as the leukocytes in this disease. (See p. 819.)

R. Poch¹ summarizes the results of his examinations of the blood in malaria as follows: At the beginning of a paroxysm of tertian or quartan fever there is occasionally an initial transitory polynuclear leukocytosis. With this exception leukocytosis is not observed in any stage of any form of malaria. Sometimes in tropical and often in tertian and quartan malaria the leukocytes are diminished in numbers during the height of the fever. Leukopenia throughout the course of the disease is not uncommon. In tertian and quartan fever all mononuclear cells are fewer during the hot stage. In all forms there is, with the fall in temperature, a relative increase in the large mononuclears which continues during the intervals and for some time during convalescence. An incompletely cured malaria may thus be detected. The eosinophiles are decreased in numbers during the paroxysm, but are usually normal at other times.

Thus it is evident that different writers disagree in regard to the findings, so that it must be assumed that quite complicated and irregular conditions obtain in this disease. However, one can in general designate as characteristic the persistent low polynuclear count, with a tendency to moderate increase in these cells at the onset of the paroxysm.

Another characteristic of malarial blood outside of the presence of the organisms is the usual occurrence of oligochromemia, often of high grade, which is caused by the direct destruction of the red cells by the parasites. In addition, all of those changes in blood morphology which are typical of the symptom-complex of so-called pernicious anemia frequently occur (megalocytosis, poikilocytosis, polychromatophilia, and basophilic degeneration of the red cells, megaloblasts, and myelocytes). The presence of pigment within the leukocytes (the large mononuclears and polynuclear neutrophils) is of importance in the diagnosis. The presence of hemoglobin in the blood-serum, with or without hemoglobinuria (black-water fever), especially after the excessive use of quinin, is also noteworthy. [Most writers in America agree in considering an increase in the large mononuclear cells a characteristic of the blood-picture in this malady.—Ed.]

Chronic Tuberculosis

This disease, if accompanied by fever and severe inflammatory phenomena, usually gives rise to a polynuclear leukocytosis. The leukocytosis corresponds roughly to the degree of inflammation, and is accordingly slight or often entirely lacking in incipient tuberculosis. From his own experience the author cannot confirm the theory that the leukocytosis depends upon a mixed infection. One often finds a decrease in the numbers of the eosinophiles and lymphocytes, varying in degree with the severity of the condition. The hemoglobin percentage and the red-cell count are often diminished in incipient as well as in advanced cases, but by no means without exception. These rules obtain for all forms of tuberculosis, whether of the lungs, lymph-nodes, bones, intestines, or serous membranes. (In regard to Tuberculous Meningitis, see p. 800.)

Acute Military Tuberculosis

In this disease the leukocyte count, though sometimes diminished, is usually normal. Leukopenia is, therefore, of no value in differentiating it from typhoid fever.

Actinomycosis

Actinomycosis may give rise to leukocytosis if there be suppuration.

Syphilis

The present hematologic investigations seem to the author to be as yet quite insufficient, because the manifestations of syphilis are not sharply enough differentiated from one another. According to Sabrazès and Mathis, there is in the initial stage a normal count or a slight increase in the mononuclear cells—according to

¹ Zeit. f. Hyg. u. Infektionskrankheiten, vol. xlii, part 3.

Löper, a lymphocytosis. In the secondary stage (with general lymphadenitis) both Sabrazès and Nägeli found a polynuclear leukocytosis and a marked increase in the mononuclear cells and transition forms.

Suppurative Affections

Suppurative processes generally lead to a marked neutrophile leukocytosis. The character of suppurative leukocytosis in perityphlitis has been carefully studied, especially by Curschmann. He differentiates—(1) Mild cases without leukocytosis or in which leukocytosis remains slight; (2) rather severe non-suppurative cases which present a transitory leukocytosis up to 22,000; and (3) severe suppurative cases which give rise to a high leukocytosis and which indicate operation. According to Curschmann, even a single leukocyte count of 25,000 is very suggestive of abscess formation, especially if it occur late in the disease. Although there are, of course, exceptions to these rules (absence of leukocytosis in very severe cases), yet, as the author pointed out in his communication to the Congress of Internal Medicine at Munich, 1895, such examinations are of great value, especially to observers of slight experience who might not realize the severity of a case from the general clinical picture. It is to be particularly emphasized, however, that one should not limit himself to a single count, but should control it by repeated examinations. In certain cases even two counts each day are to be recommended. Nägeli properly insists that not the severity of the infection, but also the reactive power of the bone-marrow, decides the degree of leukocytosis. If this be kept in mind, one will not be deceived by slight or even absent leukocytosis, but will regard it as an unfavorable sign in cases where the general clinical symptoms are severe.

Nägeli undertook an exact differential examination of the leukocytosis in perityphlitis. He found that in severe cases the eosinophiles are absent and that the percentage of lymphocytes is very low. According to this writer, any improvement soon manifests itself by the reappearance of the eosinophiles and an increase in the lymphocytes.

[Gibson,¹ in a critical study of the behavior of the leukocytes in appendicitis, reached the following conclusions: "The higher the polynuclear percentage as compared to the leukocyte count, the greater the probability of a purulent exudate. It is of value chiefly in indicating fairly consistently the existence of suppuration or gangrene. . . ." He describes a chart for representing the relation of the differential to the total count. According to Murphy,² a sudden fall in the absolute number of leukocytes with a slight decline or a rise in the percentage of polymorphonuclears is evidence of a severe infection.—Ed.]

It might be pointed out that Arneth's so-called "shifting of the neutrophile blood-picture," as well as the appearance of myelocytes observed by Schindler, are also to be considered as evidence of the severity of the infection (see below).

Leukocyte counts may be of similar practical value in the diagnosis and prognosis of pleural empyema, as well as in the diagnosis and prognosis of suppurative affections of the gall-bladder, of fat-necrosis and suppuration of the pancreas, suppurative gynecologic affections, suppurative puerperal infections, etc.

In regard to the iodine reaction of the leukocytes in suppuration see p. 787 et seq.

Trichinosis

See Eosinophile Leukocytosis, p. 808 et seq.

THE PRESENCE OF MYELOCYTES (Schindler) AND THE SO-CALLED SHIFTING OF THE NEUTROPHILE BLOOD-PICTURE IN INFECTIOUS DISEASES (Arneth)

These two studies are considered together, since both aim to show that in infectious diseases the character of the white cells, as well as their number, alters the blood picture, and that in some cases more comprehensive conclusions can be drawn from the qualitative differences than from the absolute number of the leukocytes alone. It was at first believed that conclusions as to prognosis could be drawn from the degree of leukocytosis, especially in pneumonia, in which leukocytosis has longest been recognized and best studied. This has, however, been proved impossible because, in consequence of the strong resistance of the organism, a high leukocytosis has been observed in mild infections that run a favorable course, as well as in the

¹ Annals of Surgery, April, 1906, p. 485.

² Keen's Surgery, vol. iv, p. 753.

gravest and most unfavorable cases in which the toxic irritation of the bone-marrow is intense. Thus, it appears that a slight leukocytosis may be a consequence of the lessened virulence of the pneumonic infection or of an insufficient reaction on the part of the organism. If the mere numbers of the leukocytes be considered, there results, in a way, an equation containing two unknown quantities which is impossible of solution. Another reason for the uncertain value of a mere leukocytosis is that, to a certain extent, an existing leukocytosis represents the balance between the demand for and the supply of leukocytes. Thus a definite degree of leukocytosis may result from an excessive supply and an excessive consumption of leukocytes (severe infection) as well as from a lessened supply and a diminished consumption of the same (mild infection). This statement also leads to an equation with two unknown quantities, the solution of which is necessary for the establishment of a prognosis. Both the writers make an effort to obviate these difficulties.

Schindler's Studies upon the Presence of Myelocytes in the Blood During Infectious Diseases

Besides fully developed leukocytes, Schindler¹ found also their undeveloped progenitors (the myelocytes) in the blood during leukocytosis. He rightly considered that the number of undeveloped cells presents a criterion for judging the demands made upon the bone-marrow, since manifestly only an intense toxic irritation of the latter can make such demands and cause the presence of such forms in the blood. Schindler expresses his results in regard to the finding of myelocytes in the blood in infectious diseases by the following propositions:

"1. The most varied causes (in particular those of an infectious nature) which excite leukocytosis are, in so far as they are permanent, those which give rise to a migration into the blood of large mononuclear cells with neutrophile granules (myelocytes) that normally never leave the bone-marrow. Thus we find myelocytes in pneumonia, scarlet fever, diphtheria, erysipelas, meningitis, polyarthritides, septic conditions, etc. Their mere occurrence is not always of the same significance. If they occur merely as an accompaniment of leukocytosis at the height of the same and disappear with its recession, we can infer nothing further than an insignificant expression of the ability of the bone-marrow to supply cells hastily, following the exhaustion of the existing reserves of developed leukocytes. If, however, myelocytes occur at a time when the leukocytosis has partially or quite receded, they bear witness to a functional exhaustion of the bone-marrow, the degree of which is indicated by their numeric relations to the developed cells. When the decrease in leukocytes is, together with the fall in temperature and the general symptoms of improvement, a sign of the victory of the organism over the infection, this transitory exhaustion is of no moment and is soon relieved. It is, however, of gravest significance if it supervene at a time when the infection is still fully virulent and when the organism is in greatest need of the supply of protective cells. Herein lie the grounds for the prognostic and, so to speak, practical value of the myelocytes as a measure of the normal power of the marrow to respond to stimulation. Great numbers during a falling leukocytosis and an unconquered infection are a bad sign (diphtheria, pneumonia).

"2. In the cases cited the cause of the defective leukocyte-production lies in the exhaustive paralysis which results from excessive demands (naturally, the marrow reacts at first because of its inherent properties, whether or not it becomes insufficient later). Thus, in typhoid and in malaria the cause of the leukopenia is a direct arrest of the function of the leukocyte-forming tissue through the specific influence of the toxins due to the disease—an arrest which in one case (typhoid) is permanent, in the other (malaria) is only temporary. Here again we conceive the myelocytes to be evidence of an abnormal reaction of the bone-marrow to stimulation."

Arneth's Neutrophile Blood-picture; Anisoleukocytosis

Arneth,² starting with the same ideas as Schindler (see above), undertook to make a further differentiation among the neutrophile leukocytes (formerly classed together) according to the number of nuclei, and to make this differentiation of clinical value. He used in his examinations dried smears which were fixed in absolute alco-

¹ Schindler, Studies on the Presence of Myelocytes in the Blood, I. A. D., Bern, 1904, and Zeit. f. klin. Med., 1904, vol. liv.

² Die neutrophilen weissen Blutkörperchen bei Infektionskrankheiten, Jena, Fischer, 1904.

hol for one hour and then stained for one and one-half minutes in triacid solution. Beautiful preparations were thus obtained in which even the nuclei were satisfactorily stained. In order to exclude digestive leukocytosis he took the blood either before breakfast or before the principal meal of the day.

As is well known, the terms polymorphonuclear and polynuclear are used loosely, since there are all types of transition forms between the cells in which the nuclei are quite separate and those in which they are connected by more or less broad bands. In opposition to this tendency Arneth sharply differentiates cells with one nucleus and those with two, three, four, five, or more nuclei or divisions of the nucleus. He classes myelocytes as mononuclear forms of the polymorphonuclears (p. 791), though the former are usually considered separate from this type. According to Arneth and in accord with the classification on p. 790, the remaining mononuclear forms of neutrophile leukocytes represent transition forms between myelocytes and true polynuclears. Among these transition cells Arneth differentiates those with slightly indented and those with deeply indented nuclei. He further subdivides the cells with more discrete nuclei according to the number of spheric or loop-shaped parts, a classification of less interest, which need not be considered here. Now, Arneth found that these individual types follow definite laws in normal and pathologic cases. The following table, selected from one of Arneth's examples, represents the normal neutrophile blood-picture. It should be noted that he designates the myelocytes by *M*, cells with slightly indented nuclei by *W*, and those with deeply indented nuclei by *T*.

1 nucleus. <i>M W T</i>	2 nuclei.	3 nuclei.	4 nuclei.	5 or more nuclei.	
7	39	36	16	2	= 100 per cent.

The absolute numbers represent the percentages, since Arneth always constructs his tables from a count of 100 cells in a smear. In order to understand the literature, it should be noted that loop-shaped parts of the nuclei are represented by *S* and spherical parts by *K*.

The leukocytes with two and three nuclei (Arneth's second and third subdivision) normally preponderate, as is seen in the above table. Pathologically, especially in infectious diseases, this relation is strikingly altered (or shifted) so that the number of cells to the left of the table is increased at the expense of those to the right. Arneth calls this the "shifting of the neutrophile blood-picture toward the left," and since he regards polynuclears as older and matured descendants of the mononuclears, he assumes that this shifting is brought about by the retirement of the developed cells in favor of the immature ones, just as earlier writers, especially Schindler, interpreted the appearance of myelocytes in infectious diseases. The following blood-picture obtained by Arneth in a case of angina with pneumonia is an example of such a shifting:

1 nucleus. <i>W M T</i>	2 nuclei.	3 nuclei.	4 nuclei.	5 or more nuclei.	
21	54	32	2	1	= 100 per cent.

These qualitative changes, as Arneth shows, are quite independent of the absolute number of leukocytes. Consequently, he undertakes to make the following classification of the pathologic variations in the neutrophile blood-picture, taking into consideration the presence of different combinations of the qualitative and quantitative changes. By the term isocytosis he means a normal percentage of the several varieties of neutrophile leukocytes; by anisocytosis, a qualitative change or "damage" to the normal relation.

1. Hyperleukocytosis or hypercytosis, an increase of the neutrophile leukocytes:
 - (a) Isohypercytosis, an increase without qualitative changes.
 - (b) Anisohypercytosis, an increase with qualitative changes.
2. Normoleukocytosis or normocytosis, a normal leukocyte count.
 - (a) Isonormocytosis, the same without qualitative changes.
 - (b) Anisonormocytosis, the same with qualitative changes.
3. Hypoleukocytosis or hypocytosis, a decrease in the leukocyte count.
 - (a) Isohypocytosis, the same without qualitative changes.
 - (b) Anisohypercytosis, the same with qualitative changes.

Arneth sees the cause of the anisocytosis or shifting of the blood picture to the left in the destruction of the developed leukocytes by the bacterial toxins combined with the supply of immature cells. The chief interest of Arneth's studies lies manifestly in the possibility of demonstrating changes in the neutrophile leukocytes, i. e.,

injury to the blood in infectious diseases where there is neither leukocytosis nor leukopenia, and further in demonstrating that normo-, hyper-, and hypoleukocytosis may possess a common qualitative characteristic (anisocytosis), in spite of their quantitative differences. Unfortunately, however, these new methods of study throw but little light on diagnosis and prognosis—manifestly not on the latter, because they have the same value as counting the absolute number of leukocytes. Indeed, marked anisocytosis may signify a very severe intoxication or a very favorable reactive power of the bone-marrow, *i. e.*, a well-marked resistance on the part of the organism. From observations extant we have no means of telling which of these diametrically opposed conditions it indicates. Both favorable and unfavorable cases may exhibit decided anisocytosis. For the findings in individual diseases the reader is referred to Arneth's original work.¹ The hyperleukocytosis of most infections is an anisohyperleukocytosis, just as the leukopenia caused by such diseases as typhoid and measles is an anisohypocytosis. In protracted cases of pneumonia with delayed resolution there may be anisonormocytosis, though the absolute count shows no abnormality. There is a long-continued anisonormocytosis during convalescence from measles. Isohypercytosis occurs during digestion and after cold baths and occasionally in articular rheumatism and tetanus.

Arneth's method is exacting and tedious. Numerous attempts have been made to simplify it; and, indeed, this may be done by counting (as Wolf recommends) the number of nuclei or parts of nuclei in 100 individual cells and, instead of tabulating the leukocytes according to the number of nuclei, reckoning the average, a decrease in which corresponds to shifting of the neutrophile blood-picture to the left. The advantage of this method is that changes in the blood-picture during the disease can be clearly represented by a simple curve of the average number of nuclei. Instead of this Kothe² advises counting the number of mononuclear leukocytes alone and expressing their percentage of the total leukocytes. This procedure resembles Schindler's examinations, since the myelocytes are included in counting the mononuclear cells.

Pollitzer³ and others have raised the objection that there is no proof that a decrease in the number of nuclei or parts of the nucleus is a mark of the immaturity of the cell and not a sign of the clumping of the divisions of a previously many-parted nucleus, due to injury. He also calls attention to the fact that the triacid stain which Arneth uses, being an imperfect nuclear stain, makes a clear differentiation difficult, and that with other, better, nuclear stains, cells with only one or two nuclei are not found. According to many later studies, however, there is something real at the bottom of Arneth's findings in whatever way these findings may be explained and whether one concede a diminution in the number of nuclei or merely a clumping of the divisions of the same. Besides Arneth's theory is in close accord with results of Schindler's studies on myelocytes if it be assumed that the cells with few divisions of the nucleus represent transition forms between myelocytes and mature leukocytes. The author does not wish to join in the debate, but would remark that, so long as the above objections to Arneth's examinations are maintained, Schindler's studies possess a firmer basis, since myelocytes are more surely differentiated in well-stained and even triacid preparations and are recognized as the ancestors of the neutrophile leukocytes. It is remarkable that though Arneth's findings have been rather exhaustively discussed, very little attention has been paid to Schindler's studies. This is due chiefly to the fact that myelocytes are, as a rule, so few (usually only a fraction of 1 per cent., and even in pneumonia and malaria only as high as 1.6 per cent. and 2.5 per cent. respectively) that one must count very many leukocytes in order to form a proper judgment of the proportion of myelocytes. Later investigators, however, have found higher and easily determined percentages of these cells; thus in diphtheria Engel found 10 per cent., and in sepsis complicated by anemia Nägeli found 25 per cent.

OTHER POLYNUCLEAR NEUTROPHILIC LEUKOCYTOSES

Toxic and Medicinal Leukocytosis.—This is observed chiefly in poisoning with the blood-poisons, potassium chlorate, phenacetin, and arsenic, after chloroform, and in hemoglobinuria. These conditions have not been especially studied.

¹ See the monograph cited above, *Münch. med. Woch.*, 1904, No. 45; *Zeit. f. klin. Med.*, 1905, and *Die Lungenschwindsucht auf Grund klinischer und hämatologischer Untersuchungen*, Leipzig, Barth, 1905. In the last a number of other works are quoted.

² *Berlin. klin. Woch.*, 1908, No. 36, p. 1633.

³ *Wien. klin. Woch.*, 1906, No. 4, and *Arch. f. klin. Med.*, 1907, vol. xcii.

Among the drugs which produce a polynuclear neutrophilic leukocytosis when used internally are antipyrin and antifebrin. The pilocarpin leukocytosis seems to be mainly a lymphocytosis. (See p. 809.)

Tuberculin injections lead to a leukocytosis, the appearance of which, according to the author, is associated with, and a much more delicate test than, the other phenomena of a reaction. Blood-examination may, therefore, be used with advantage to control tuberculin injections for therapeutic purposes. They are much simpler and less time consuming for this purpose than Wright's estimation of opsonins. The author's observations in this regard are based upon Beraneck's tuberculin. Fanconnet does not confirm the lymphocytosis and eosinophilia which some writers have insisted follow the use of tuberculin.

Anemic Leukocytosis.—This is observed chiefly after acute loss of blood (posthemorrhagic leukocytosis) and in those types of anemia where the bone-marrow is in a state of increased regenerative activity (secondary anemia). The polynuclear neutrophilic cells are chiefly affected. The leukocytosis may be very marked. It disappears when the loss of blood has been replaced by regeneration.

Cachectic Leukocytosis.—This is polynuclear and neutrophilic, and is observed chiefly in malignant tumors—carcinoma and sarcoma.

Agonal Leukocytosis.—This has been observed shortly before death from various diseases, even in those which in themselves, as a rule, produce no leukocytosis. Ehrlich and Lazarus do not regard this as a true leukocytosis, but claim that the white corpuscles are deposited in the peripheral vessels on account of the general depression of the circulation. This accumulation affects chiefly the polynuclear neutrophiles.

EOSINOPHILE LEUKOCYTOSIS, OR EOSINOPHILIA

This is not only a relative, but an absolute, increase of polynuclear eosinophilic leukocytes. The total leukocyte count may be normal or increased. In the latter case the neutrophiles are also usually increased. This condition may be called eosinophilia plus neutrophile leukocytosis, whereas an increase in the eosinophiles alone may be termed simply eosinophilia. The number of eosinophiles is normally 140 to 280 per cubic millimeter, *i. e.*, 2 to 4 per cent. of the total number of leukocytes. They may increase up to 5000. It must be borne in mind, in estimating the degree of eosinophilia, that the eosinophiles are more numerous in children than in adults. A pathologic eosinophilia is observed:

1. In *bronchial asthma* and "eosinophile" bronchitis, which occurs especially in emphysema. The eosinophiles may be increased up to 20 per cent. of the total number of leukocytes.

2. In *pemphigus*, Zappert found 4800 eosinophiles in a cubic millimeter.

3. In various other *cutaneous diseases* (urticaria, prurigo, eczema, mercury dermatitis). Lazarus found 60 per cent. of the leukocytes to be eosinophiles in a case of urticaria.

4. In *multiple blastomycosis* (yeast-fungus infection) Harter and Lucien found an eosinophilia of 18 to 23 per cent. of the general leukocytosis.

5. In certain forms of *neurasthenia* and nervous diarrheas (Nägeli).

6. In *helminthiasis* [ankylostoma, ascaris, oxyuris, bothriocephalus, tenia, anguillula stercoralis and intestinalis (strongyloides intestinalis), trichocephalus, and perhaps in other intestinal parasites, as well as echinococcus and cysticercus, trichina, filaria sanguinis, distomum hæmatobium (bilharzia)]. Eosinophilia has been observed in intestinal helminthiasis, especially when Charcot's crystals are present in the stools (p. 521 et seq.). The diagnostic significance of this finding is manifest. The eosinophiles disappear immediately after the death of the echinococcus.¹ According to the last writer, persistence of eosinophilia after operation indicates the presence of still unopened cysts. The eosinophiles disappear if the disease (ankylostomum, bothriocephalus, and rarely tenia and trichocephalus) causes too severe an anemia. The author's observations, however, do not agree with the statement that eosinophilia is absent (especially in bothriocephalus disease), even before anemia supervenes. The truth is that in this infection eosinophilia is not so constant as in the other forms of helminthiasis. For the complete blood-picture caused by these parasites see p. 840 et seq.

In *trichinosis*,² since eosinophilia is present in the overwhelming majority of

¹ Chauffard and Bodin, Bull. de la soc. med. des hôp., 1907, p. 1473, and Rosello, Comptes rend. de la soc. de biol., 1907, lxiii, p. 423.

² [Brown, Johns Hopkins Hospital Bull., April, 1897, was the first to call attention to the diagnostic value of eosinophilia in trichiniasis.—Ed.]

these cases, it is of the greatest diagnostic importance,¹ especially in differentiating this affection from typhoid fever, in which the eosinophile cells entirely disappear at the height of the disease. In trichinosis the number of eosinophile leukocytes after the fourteenth day may be increased to 40 to 50 per cent. of the total number (Schleip). The absolute number of total leukocytes is not always increased. In 7 cases of human trichinosis Stäubli also found a very high percentage of eosinophiles. In animal experiments the eosinophilia appeared on the seventh day after the ingestion of infected meat. Stäubli found a very high general leukocytosis in severe cases in man. The neutrophiles as well as the eosinophiles are increased in numbers. The lymphocytes behave as in typhoid, *i. e.*, they are first diminished and then persistently increased in numbers. In both men and animals the occurrence of polycythemia and polychromemia has been demonstrated at the beginning of the infection. Later on this condition gives way to a slight grade of anemia. In severe cases, as well as in mixed infections, the eosinophiles may be absent or may disappear after persisting for a short time. In regard to the possibility of the occurrence of trichina embryos in the blood see p. 822 et seq.

7. *Post-febrile Eosinophilia*.—After the disappearance of the fever in many infectious diseases, especially if accompanied by the ordinary neutrophile leukocytosis (pneumonia, acute rheumatism, malaria). In scarlet fever the eosinophiles are increased not only after the fever has vanished, but during the fever also. In regard to the alleged eosinophilia after injection of tuberculin see p. 808.

8. In malignant tumors leading to cachexia.

9. After removal of the spleen and in chronic tumors of the spleen.

LYMPHOCYTOSIS

This name is applied to those conditions of the blood where there is an increase of lymphocytes, but it does not include the lymphocytosis of lymphatic leukemia, which is sufficiently characteristic to be termed an independent disease. We know very little as yet about the occurrence of a pure lymphocytosis. It should be mentioned, however, that in some conditions or ordinary polynuclear leukocytosis, for instance, in the leukocytosis of digestion, the lymphocytes may also be increased, and that in the new-born the physiologic leukocytosis is a lymphocytosis. Pathologically, a lymphocytosis occurs in whooping-cough (p. 802) and in a certain stage of typhoid (see p. 799), as well as at the end of many other infections. (See p. 797 et seq.) Lymphocytosis has been observed after injection of pilocarpin. A lymphocytosis is of an entirely different clinical significance from a polynuclear leukocytosis, not only because the former cells are derived from the lymphatic glands and have a function quite different from the latter, but also because, on account of their slightly developed ameboid contractility, their origin must be attributed, according to Ehrlich and his school, rather to a mechanical washing out of the lymphocytes from the lymphatic glands, and to anatomic changes in the latter structures than to chemotactic irritants in the blood. In contradistinction to the earlier supposition, it should be noted that recent observations indicate that the lymphocytes are by no means immobile.

In regard to the alleged lymphocytosis following tuberculin injections see p. 808.

BLOOD-PLATELETS

Bizzozero and Hayem have recently demonstrated that the granules and clumps of granules visible in any fresh blood-preparation are postmortem formations which owe their existence to rapid disintegration of the elements called blood-platelets or hematoblasts.

¹ See Schleip, 75, Naturforscherversammlung, 1903, ref. in Berlin. klin. Woch., 1903, No. 41, p. 946, and Arch. f. klin. Med., vol. lxxx, and Stäubli, Deut. Arch. f. klin. Med., 1906, vol. lxxxv, pp. 286-341.

These blood-platelets (Pl. 7, Fig. 41) are small, circular or oval, colorless structures, about $3\ \mu$ in diameter. They disintegrate very easily, and adhere very readily to each other and to the other elements of the blood. They play an important part in the etiology of white thrombi. Their number is variously estimated at from 200,000 to 500,000 per cubic millimeter. If only elements which are stained by methyl-violet are counted, their number, according to the estimations made at the author's clinic, varies between 150,000 and 200,000. In harmony with Bizzozero, Deckhuyzen and Deetjen have shown the corpuscular character of the platelets and the presence of nuclei in them, and have sharply differentiated them from certain structures arising from the disintegration of leukocytes and red cells with which they were formerly confused.

For the purpose of examining blood-platelets before they are destroyed, it is necessary to add some preservative fluid to the blood the moment it is drawn. Hayem recommends the following:

(1) A solution of 1 part of methylene-violet and 5000 parts of 75 per cent. (physiologic) solution of sodium chlorid. (See, however, p. 768.)

(2) A mixture of 1 part of a 1 per cent. aqueous solution of osmic acid and 2 parts of 0.75 per cent. solution of sodium chlorid. The latter fluid fixes the blood-platelets permanently, whereas the former stains them. Bizzozero puts a drop of one of these solutions on the finger-tip, the skin of which has been carefully cleansed. The skin is then punctured through the fluid, so that the elements of the blood come in immediate contact with the fluid. This blood-mixture is placed under the microscope; the characteristic blood-platelets are then seen, but no granules.

A much better method which permits the demonstration of their disputed ameboid movements is as follows: Blood obtained by puncturing a vein is collected in a small graduate containing a solution of 0.001 gm. hirudin in 5 cc. water. After it has stood a short time a smear is made from the upper layers which is free from corpuscles, but swarming with platelets. A cover-slip rimmed with vaselin is placed on the smear, and the latter is examined on a warm stage with the oil immersion. The ameboid movements of the platelets as well as their morphology can be observed.

Formerly, blood-platelets were counted in a very similar way to the red blood-corpuscles. Bizzozero, however, believes that if this method of counting blood-platelets be used, a considerable number adhere to the side of the pipet. He, therefore, advises that the blood be received directly into a 14 per cent. solution of magnesium sulphate, according to the technic described above. The blood-platelets are a little deformed, to be sure, but this solution, by coagulating their protein, reduces their tendency to clump, and, therefore, keeps them isolated. The ratio between red blood-corpuscles and blood-platelets can then be estimated by the Thoma-Zeiss counter, the number of red blood-corpuscles determined in the usual way, and the absolute number of blood-platelets then reckoned. Bizzozero's method is followed at the Bern clinic with the modification of adding to the 14 per cent. magnesium sulphate solution enough methyl-violet to stain the platelets, and only those elements thus stained are counted (see above). Affanasiew has recommended the use of a solution consisting of 0.6 per cent. sodium chlorid with 0.6 per cent. peptone and a little methylene-violet. The number of blood-platelets may also be found by a determination of the ratio between it and the number of the leukocytes in a dry preparation; the disadvantage of this method is that the blood-platelets are found, clumped, and are not always easy to distinguish from precipitate.

These methods of blood-platelet-counting possess many difficulties, the greatest of which is that the platelets cannot always be absolutely differentiated from disintegration products of the other formed elements of the blood. Besides, it may be that because of their small size they do not fall promptly to the bottom of the counting chamber, and must, therefore, be looked for at different levels of the fluid. Further, it is impossible to employ the powerful objectives which are essential for exact recognition of the platelets, because of the depth of the ordinary counting-chamber. Helber¹ has devised a method which overcomes these difficulties. He uses a counting-chamber² which is only 0.02 mm. deep. With this cell and the accompanying thin cover-slip the stronger objectives (preferably Zeiss E) may be used, and with a compensating ocular (No. 12) a magnification of 1080 diameters, which is sufficient to distinguish platelets from similar structures can be obtained, ocular (No. 6) is practically strong enough. Helber makes a dilution of 1:30 in a specially constructed pipet, using a 10 per cent. solution of sodium metaphosphate, which preserves the platelets well. When a drop of the dilution is placed in the counting-chamber, the platelets can be easily recognized among the red cells as colorless bodies one-third the

¹ Deut. Arch. f. klin. Med., vol. lxxxi, p. 316.

² Made by Zeiss in Jena.

size of the latter, round or oval in shape, and with a darker central portion, the nucleus. A satisfactory dilution must appear in the ampulla of the pipet to be clear by transmitted light and slightly turbid (ground color) by strong direct light. In Helber's counting-chamber one can count red cells, platelets, and leukocytes at the same time, though the number of the latter is hardly sufficient on account of the shallow cell. By this method Helber found about 200,000 to 250,000 plates per c.mm., which corresponds approximately to earlier estimates.

[Pratt¹ recommends the following technic: A clean platinum loop is filled with a 2 per cent. solution of sodium metaphosphate in physiologic salt solution and just touched to the top of a drop of blood obtained by pricking the lobe of the ear. The mixture is transferred to a slide and at once covered with a clean cover-slip. The ratio of platelets to red blood-corpuscles is then determined, and from the actual number of red corpuscles, counted in the usual way, the actual number of platelets is estimated. J. H. Wright counts the actual number of platelets as follows: The blood from a finger-prick is diluted 1 : 100 in a red-cell pipet with a mixture of equal parts of a solution of brilliant cresyl blue (1 : 300) and potassium cyanid (1 : 1400), the pipet is well shaken, and a drop placed in the counting-chamber and covered with a very thin, specially made cover-glass. One must wait at least ten minutes to allow the platelets to settle before counting.—Ed.]

Little is as yet known regarding the relation of blood-platelets to pathologic conditions. According to Bizzozero, they are increased in pregnancy, after the loss of blood, in chlorosis, in tuberculosis, cholera, etc. They are diminished in the fever of acute diseases, but, according to Hayem, increase toward the end of a fever (*crise hématoblastique*). Denys observed a diminution of blood-platelets in purpura. Helber found them increased in mild anemias and diminished in the severe irreparable forms of anemia. (See p. 781 with reference to the Iodin Reaction of Blood-platelets.)

HEMOKONIA OR BLOOD-DUST

Blood-dust and hemokonia are names given to very minute granules which are always found in the blood and blood-serum. They are the size of the smallest bacteria, therefore much smaller than platelets and not to be confused with them. They exhibit Brownian movement. Their composition is still under discussion; in any case they consist in great part of fat (see Lipemia). Some of them, however, stain with nuclear dyes and are, therefore, thought to be derived from nuclei. Their origin has even been thought to be the granules of the leukocytes. In regard to the literature, see Nägeli's works.²

MELANEMIA

By *melanemia* is meant the presence of granular brownish or black pigment in the blood. It is usually found in the interior of white blood-corpuscles, which are often irregular in shape, and less frequently as free plates between the cellular elements of the blood. Melanemia has as yet been found only following malaria, especially long-continued malarial cachexia, and in recurrent fever. In malaria (see pp. 802 and 819) the pigment derived from hemoglobin may show all shades of color from red to black. The presence of white blood-corpuscles with pigment or of free pigment is of great diagnostic importance in those cases in which the malarial parasites are not readily demonstrable.

LIPEMIA

Blood always contains some fat under physiologic conditions. More marked lipemia is observed physiologically during digestion, and pathologically in chronic alcoholism, in acute phosphorus-poisoning, in severe diabetes, and in fractures which lead to fat-emboli. If the blood contain a considerable amount of fat, its pallor and cloudiness are apparent to the naked eye. Under the microscope the fat is usually seen in the form of very fine granules (blood-dust), just as in chyle; in embolic lipemia distinct light-refracting droplets may be seen. They are stained black by osmic acid, and red by Sudan III, and dissolved in a dry preparation by the addition of ether.³ Even absolutely clear serum obtained from fasting individuals contains fat. It must be supposed that this is either dissolved in some unknown way or that it is present in a colloidal state or so finely emulsified that it is invisible.

¹ Jour. Amer. Med. Assoc., Dec. 30, 1905, p. 1999.

² Nägeli, Blutkrankheiten und Blutdiagnostik, Leipzig, Veit and Co., 1908.

³ Rieder, Arch. f. klin. Med., vol. lix, p. 444.

In a recent study of physiologic or digestive lipemia E. Neisser and H. Bräuning¹ reach the following conclusions: (1) The blood-serum of a man after a twelve-hours' fast is clear. (2) In the clear serum of a fasting man fat is present in solution or as a colloid or in such fine suspension that it cannot be perceived. (3) After the ingestion of a moderate amount of fat (equal to that taken in an ordinary meal) the serum is turbid; after any other food, clear. (4) In order to obtain clear serum the blood must be withdrawn after the patient has eaten no fat for twelve hours. (5) The turbidity of the serum after the ingestion of fat is due to an extremely fine suspension of this substance therein (hemokonia). (6) A layer of fat is formed in the serum after butter has been administered, from the thickness of which one may form an estimate of the hemokonia content. (7) The turbidity begins one to two hours after administration of milk-fat, reaches its height in about six, and disappears in eight to ten, hours. (8) The degree of turbidity varies with the kind of fat ingested and with the species of animal which ingests it. (9) In pathologic cases with diminished fat absorption the serum does not become turbid after the administration of fat.

The author would call attention to the significance of this last fact in the diagnosis of pancreatic disease and in cases when the bile in the intestine is diminished.

THE DEMONSTRATION OF BACTERIA IN THE BLOOD

DIRECT MICROSCOPIC DEMONSTRATION OF BACTERIA IN THE BLOOD

To demonstrate bacteria in the blood directly, dry preparations may be spread between two cover-slips in the usual way. It is even better to use slides, so that the largest possible amount of blood may be studied. Such preparations can be exam-

Fig. 308.—*Spirochaeta* of relapsing fever (*Spirochaeta Obermeieri*) in blood. Photograph by Weichselbaum ($\times 1000$).

Fig. 309.—Anthrax bacilli in blood, unstained ($\times 430$) (Fränkel).

ined without cover-slips. The slides are fixed by passing them through the flame two or three times, and then stained like specimens of sputum. (See pp. 709, 715 et seq.)

Since the staining of the erythrocytes and of the dried albumin of the blood interferes with the beauty and transparency of the preparations, the procedure suggested by Günther² may be followed with advantage, as by it the hemoglobin and part of the albumin are removed from the dried specimen. Günther fixes the dried blood by heat, and then washes it for ten seconds in a 5 per cent. solution of acetic acid. The cover-glass is then dried, and for several seconds its smeared side is held directly over an open bottle of ammonia, which has been previously well shaken, so that the last remains of the acid may be neutralized. It is now immersed in the staining solution for a short time and then washed in water. Since the tinctorial characteristics of the erythrocytes depend upon their contained hemoglobin, these structures will appear colorless, and any bacteria present will be easy

¹ Zeit. f. exper. Path. u. Therap., 1907, vol. iv.

² Fortschritte der Med., 1885, vol. iii, p. 756.

of recognition. Nöggerath's and Stähelin's centrifuge method for demonstrating *Spirochæta pallida* (p. 816) may be of service in demonstrating also small numbers of bacteria in the blood.

Another method, devised by Löper and Louste,¹ consists of mixing a drop of blood with 1 cc. absolute alcohol and 2 cc. distilled water and centrifuging. The red cells are thus dissolved and bacteria can be demonstrated in dry preparations of the sediment.

The *bacilli of anthrax* (Fig. 309) are pathognomonic when found in the blood. They may be recognized in unstained specimens. For culture methods, see p. 814.

Bacteria are more easily demonstrated in the blood by cultures than by a microscopic examination, *e. g.*, the streptococci and staphylococci (compare Figs. 284 and 285) found in septicopyemia. The number of micro-organisms found in the blood is always comparatively small, so that considerable blood should be employed to inoculate the culture-medium. For this purpose a sufficient quantity of blood is removed from some vein of the arm with the aid of a small syringe fitted with an asbestos piston and thoroughly sterilized. This syringe should contain about 5 cc. The skin should be first carefully disinfected with alcohol and corrosive sublimate. About 1 cc. of this blood is added to a tube of agar (liquefiable at 40° C. at the most), to one with 10 per cent. gelatin, and to two bouillon tubes. The fluids are carefully shaken, and the agar and the gelatin tubes are plated. The agar plates and the bouillon tubes are placed in the incubator at 37° C., the gelatin plate at 22° C., Sittmann² found pus-cocci or staphylococci in the blood in every case of septic pyemia which he examined in this way. The bacteriologic examination of the blood is the most accurate aid for determining pyemia.

In severe cases of pneumonia we have not infrequently been able to demonstrate pneumococci in the blood by direct microscopic examination of dry preparations. This shows the relationship existing between pneumonia of the human subject, which is usually regarded as a purely local affection, although it is really very often accompanied with a general blood infection, and the pneumococcic sepsis of laboratory animals. Günther's process, given upon p. 812, for the removal of the hemoglobin with acetic acid, greatly aids the demonstration of the capsules of the pneumococci. Wiens (see below) considers that pneumococci can be demonstrated in the blood of most all patients with pneumonia provided his culture method be employed (fluid media).

Typhoid bacilli may frequently be demonstrated in the blood of typhoid fever patients, either in fresh specimens or in cultures, and, as the author can testify, may even be found in cases running a mild course. They are most frequently found in the first week of the disease.

Pöppelmann³ claims that even quite early in the disease typhoid bacilli can be found in the blood if a number of smears from a large drop of blood be examined. He uses Jenner's stain (see p. 778 et seq.), without special fixation. The bacilli are colored blue. The culture method, however, is more often successful (see below).

Even *meningococci* have been demonstrated in the blood of patients with epidemic meningitis (Rusca, in the author's clinic).

The demonstration of *pest bacilli* Fig. (289) plays an important rôle in the diagnosis of bubonic plague. (For their recognition the reader is referred to the section upon Examination of the Sputum.)

The occurrence of the *Bacillus mallei* (p. 721) in the blood is of less diagnostic importance.

Tubercle bacilli (p. 709) have as yet been found in the blood only in acute miliary tuberculosis, and then in very small numbers.

Staphylococci and *streptococci* can, as a rule, be recovered from the blood only by culture. (See p. 719 et seq.)

Micrococcus melitensis (Bruce), which is the cause of Malta fever (a disease occurring in Malta, the Mediterranean countries, India, China, and Japan), can sometimes be demonstrated in the blood. It is a very small organism (about 0.3 μ in diameter), elliptic in form. It is doubtful whether it should be described as a coccus or a short bacillus. It is non-motile and Gram-positive. Scanty growth can be obtained on agar. It does not liquefy gelatin. It is best recovered from the blood by culture. The agglutination test is also of importance (p. 862).

CULTURAL DEMONSTRATION OF BACTERIA IN THE BLOOD¹

In many cases bacteria can be demonstrated in the blood only by culture. This is particularly true of staphylococci and streptococci. Since they are often present in small numbers, a large amount of blood must be used in order to insure satisfactory results. Sittmann² recommends the following procedure: By means of a sterile syringe with an asbestos plunger, 5 cc. of blood are withdrawn from a distended vein in the bend of the elbow after careful disinfection of the skin with alcohol and bichlorid solution. One cc. of this is placed in nutrient agar, which has been liquefied and then cooled to 45° C., 1 cc. in nutrient gelatin (containing at least 10 per cent. of gelatin), and the remainder in 2 tubes of bouillon. The contents are immediately mixed by gentle agitation so as to avoid foaming, and the gelatin and agar tubes emptied into Petri dishes. The agar plate and the bouillon tubes are kept at 37° C. The gelatin plate is inverted to prevent the washing away of the colonies by the water of condensation and kept at 22° C. Lenhartz³ uses still larger amounts of blood. This writer withdraws 20 to 30 cc. by means of a 30 cc. syringe with a glass plunger (Luer), and a cannula 6 to 7 cm. long and of not too small a bore, both sterilized dry.⁴ After the vein has been entered the blood flows in without suction by virtue of its own pressure and displaces the plunger. The blood obtained is divided among 3 liquefied gelatin tubes and 3 tubes containing at least 10 cc. each of a liquefied agar cooled in a water-bath to 45° to 43° C. The blood and media are then mixed as uniformly as possible, care being taken to prevent foaming; each individual tube is emptied into a Petri dish, the gelatin plates kept at room temperature, and the agar plates at incubator temperature. In order to obviate any disturbances caused by the water of condensation, the covered plates are put away bottom upward. The growing colonies are easily seen by transmitted light. They usually seem to be dark green, but this, as the author has convinced himself, is merely because they are contrasted with the intense red of the blood-containing layers of the medium. Virulent streptococci are characterized by the fact that they deprive the medium of color in the immediate vicinity of the colonies. Non-pathogenic streptococci do not do this. (See p. 720.)

Wiens⁵ has pointed out that the employment of fluid media is much more advantageous than the Sittmann-Lenhartz plate method, especially for the demonstration of pneumococci, since the results are much more frequently positive; indeed, according to Wiens, constantly so. He recommends an aqueous solution of 1 per cent. pure commercial peptone and 1 per cent. of dextrose. The reaction of the medium should be only very slightly alkaline. At least 1 cc. of blood is mixed with each tubeful of this fluid medium. After twenty-four hours' growth the culture is streaked on agar plates. The obvious disadvantages of this method are that no sure estimate of the numbers of bacteria can be made, and that errors may easily arise through contamination. The latter, however, may be avoided if several tubes be inoculated and if only similar results be credited.

Kayser and Conradi have recommended the culture of typhoid bacilli on sterilized bile to facilitate their growth, and the preparation of agar plates from this culture.

In accord with the fact that pneumococci, in contradistinction to streptococci, are disintegrated by bile⁶ (the only point of difference between the former and certain forms of the latter), Wiens found that pneumococci could not be cultured from the blood if bile media were used.

[A simple procedure, if it be desired to cultivate the organism on several media, is to collect the blood at the bedside in a sterile solution containing 2 gm. ammo-

nium oxalate and 6 gm. sodium chlorid in 1 liter of water¹ or in a 1 per cent. solution of sodium citrate, and to distribute the mixture among the various media in the laboratory.—Ed.]

THE DEMONSTRATION OF SPIROCHÆTÆ IN THE BLOOD

Spirochætæ are screw- or spiral-shaped organisms whose biologic classification is uncertain. They were formerly classed as bacteria, while recently the tendency has been to regard them as protozoa,² or at least a group between the protozoa and bacteria, on the boundary line between the animal and vegetable kingdoms. The question cannot yet be definitely decided. The old name *spirilla*, which is still used here and there, should be replaced by the new term, *spirochæta*, since the use of the former causes confusion with the species *spirillum* of the genus *bacteria*. *Spirochætæ* were indeed formerly included in this species of the bacteria because they resemble the *spirilla* in form.

Spirochæta Obermeieri (*Spirochæta* of Relapsing Fever, Formerly Called *Recurrents Spirilla*).—This micro-organism (see Fig. 310), discovered by Obermeier as far back as 1868, is the cause of relapsing fever (relapsing typhus, *febris recurrens*, or, briefly, *recurrens*), a disease formerly wide-spread throughout Europe, but since the Seven Years' War, present only in European Russia, and to a greater extent in Asia and in Africa. It is characterized by the alteration of febrile and afebrile periods (see curve, p. 82), by enlargement of the spleen, and frequently by a slight degree of icterus. R. Koch has shown that the *spirochæta* of African relapsing fever is transferred to man by many varieties of ticks, especially the *Ornithodoros moubata* (Murray), which live in the grasses. European relapsing fever, which differs very little from the African form, is transmitted by bedbugs and perhaps also by fleas and lice. Whether ticks also should be included here is not known. In the African form the ticks transmit the disease to their eggs and so increase their ability as contagion carriers. The disease can be experimentally transmitted to monkeys. The parasites can, under some circumstances, be found even in fresh preparations of the patient's blood. Though it is at times difficult to identify them absolutely because of their brisk movements, this very quality makes their detection easy. The movements consist in a twisting motion around the long axis, lateral motion, and forward motion in the direction of the long axis. Sometimes the unstained *spirochætæ* are first clearly seen after the movement is somewhat slackened. Examination of stained preparations is easier. The common bacterial stains are suitable, but Giemsa's is the most satisfactory. The usual technic is followed after fixation by alcohol and osmic acid (osmic acid vapor, see below, under *Spirochæta pallida*). Günther recommends fixing the cover-glass preparations for one hour at a temperature of 75° C., laying them in 5 per cent. acetic acid for five seconds, removing this by washing in water, and passing the cover-glass to and fro over ammonium hydrate solution, and finally staining with gentian violet. Nöggerath's and Stähelin's centrifugalization method (see p. 816) for demonstrating *Spirochæta pallida* may also be recommended. The *Spirochætæ Obermeieri* are about 1 μ thick and 10 to 30 μ long. They are usually scanty in the afebrile periods, appear shortly before the onset of the fever, occur in large numbers at the beginning of the fever, and almost or quite disappear again with the crisis. They are found in greatest numbers on the second day of fever. In extravascular blood they are soon clumped (agglutinated) and then destroyed.

Fig. 310.—*Spirochæta* of relapsing fever (*Spirochæta Obermeieri*) in the blood. Microphotograph after Weichselbaum (1000 \times 1).

¹ Epstein, Amer. Jour. Med. Sci., Sept., 1907, p. 436.

² [See, however, the exhaustive studies of Norris, Pappenheimer, and Flournoy (Jour. Infect. Diseases, May, 1906, p. 266), who claim that they must be considered bacteria or, at least, in a class by themselves; and those of Novy and Knapp (ibid., p. 291), who reach the same conclusions.—Ed.]

Spirochæta Pallida of Syphilis (Schaudinn).—One can hardly doubt to-day that the *Spirochæta pallida* (also termed *Treponema pallidum*, see Fig. 311), discovered by Schaudinn, is the exciting cause of syphilis. Although this organism is found chiefly in the tissue juices of syphilitic lesions, it has been detected in the blood in the secondary stage of early cases, and even in hereditary syphilis, so that the methods for demonstrating it therein must be considered. Dried preparations are usually employed. They are fixed for one minute in vapor of osmic acid by inverting the slide over a dish filled with the acid, stained in the usual manner with Giemsa's solution for one to two hours (see p. 779), washed, and then examined directly with the oil immersion or first mounted in Canada balsam.

The following methods are also reliable:

Lesser¹ dries the smears in air, fixes them for five minutes in absolute alcohol, and floats the cover-slips for at least an hour on a mixture of 15 drops of Giemsa's solution and 10 cc. distilled water. They are then washed, dried, and examined with the oil-immersion.

Preis² fixes by passing the slide three times through the flame, and holds the slide with two clean Cornet forceps. Should the teeth of the forceps be soiled by another dye, the entire preparation is spoiled. He then floods the slide with a mixture of 25 drops of Giemsa's solution in a third of a test-tube full of water, and moves it slowly back and forth about 5 cm. above the flame, until the fluid steams moderately. (It must not boil.) He then washes and repeats the process three or four times with the remainder of the solution. The quicker the procedure, the better does the stain succeed. The stained preparation is then quickly washed in two changes of water and immediately dried with filter-paper. The staining must be such that the

Fig. 311.—*Spirochæta pallida* or *spirochæta* of syphilis (after Lesser). One specimen of *Spirochæta refringens* to the left and one to the right (Schaudinn).

red cells (which appear granular) have the faintest pale pink tinge. If so, the stain is satisfactory and the *spirochætæ* can be clearly recognized. Otherwise the staining must be repeated on the same preparation.

Nöggerath and Stähelin³ give the following directions: At least 1 cc. of blood from the lobe of the ear or a vein is dropped into ten times its volume of 0.1 per cent. acetic acid and centrifuged. Smears are made from different layers of the sediment and stained with Giemsa's solution.

Spirochæta pallida is stained a pale pink (therefore, the name *pallida*), while other *spirochætæ* assume a bluish tint. It differs from other, saprophytic, *spirochætæ*, and especially from *Spirochæta refringens*, which often occurs with it in superficial lesions, by its more numerous and sharper kinks. At either side of Fig. 311 is shown an example of the latter species, which is recognized by its flatter curves, and in stained smears by its different color. Living *spirochætæ* can be demonstrated in unstained preparations by means of the ultraviolet microscope; indeed, they are easily recognized because of their mobility. The sediment obtained by the Nöggerath-Stähelin method can also be used in the ultraviolet microscope, but, of course, all movement is inhibited by the presence of acetic acid.

THE BLOOD IN MALARIA; MALARIAL PLASMODIA⁴

We owe our knowledge of the malarial parasite, first of all, to the pioneer investigations of the French military surgeon Laveran. Further development in the study of the etiology of malaria has been accomplished chiefly by Italian in-

¹ Lehrbuch der Harn- und Geschlechtskranken, 1906, twelfth ed.

² Wien. med. Presse, 1906, No. 49.

³ Münch. med. Woch., 1905, No. 31, p. 1481.

⁴ [The reader is referred to Thayer's Lectures on the Malarial Fevers, Appleton, 1897, and to Deaderick's A Practical Study of Malaria, Saunders, 1909.—Ed.]

investigators, especially Golgi, Marchiafava, and Celli, and recently by R. Koch and many others. Of the comprehensive articles upon this topic, may be cited the monographs of Mannaberg,¹ which contain what was known to 1899 and numerous original observations. L. Reinhardt's² monograph contains a short résumé of the most recent work on the subject.

The knowledge of the most important data concerning the parasites has been obtained from the examination of fresh unstained specimens in which, with the aid of an oil-immersion lens, most of the details described below can be quite easily recognized.

Malarial parasites, ordinarily called plasmodia, are unicellular organisms belonging to the class of sporozoa, subclass hemosporidia, which are on the borderline of the animal and the vegetable kingdoms. They consist of small masses of protoplasm, the diameters of which vary between 1 and 10 μ , according to the age and species of the individuals. The younger specimens are often ring-formed (see Pl. 5, Fig. 3, No. 37), and show active ameboid motion. They develop in the interior of the red blood-cells, destroying their host in their growth. They alter the hemoglobin of the blood-corpuscles which they inhabit to a brownish-black pigment. This pigment is generally visible in the interior of the parasite, undergoing active dancing motion, which may partly depend upon the intrinsic motion of the protoplasm, and should not be confounded with the much slower ameboid motion of the organism. After the parasite has reached a certain stage of development within the red blood-cell, and has more or less completely consumed the latter (Pl. 7, Figs. 1 to 4, 11 to 13, and Pl. 5, Fig. 3, Nos. 36 and 37), it multiplies by merulation (Pl. 7, Figs. 5 to 8 and 16). This takes place by a process of division (see below), varying in the different types, but always in such a manner that nothing remains of the mother organism but the pigment. The free pigment is taken up by the white blood-corpuscles, and, when these are subsequently disintegrated, is deposited in the organs (melanemia). The young parasites produced by subdivision were formerly erroneously known as spores. They differ from the fully developed parasites only in their size, and have none of the characteristics of true spores (Pl. 5, Fig. 3, No. 39, and Pl. 7, 8). They penetrate fresh blood-corpuscles, and then repeat the stages of development. The type of development of the quartan malarial parasite is represented in Plate 7, Figs. 11 to 16; of the tertian organism, in Figs. 1 to 8. The attacks of fever so characteristic of malaria are, generally speaking, associated with merulation of the parasite. These paroxysms follow at regular intervals in the ordinary types of malaria, because the time for the cycle of development of one generation of parasites is a definite quantity which can be usually expressed in terms of days, *e. g.*, tertian and quartan. Types with longer periods (quintan) are more uncommon, and not so thoroughly understood. Most quotidian types, at least in regions where tertian and quartan fever prevail, represent *composite* forms which arise by different generations of tertian or quartan parasites developing in the organism on succeeding days, the one generation being a day older than the other. A quotidian type of fever will be observed if two generations of tertian or three generations of quartan parasites complete their cycle of development on days succeeding each other. This view of quotidian types was prevalent even before the parasite of malaria was discovered, because the attacks were peculiarly grouped together in pairs with reference to their severity and other symptoms (*tertiana duplex*, *quartiana triplex*). This clinical conception was confirmed by the result of Golgi's study of the parasitic development in the blood. Besides these combined quotidian types, a *true quotidian* type, whose cycle of development lasted only one day, was supposed to exist, until in recent times the investigation of R. Koch³ (given more in detail below) disproved this idea.

Our knowledge of the morphologic conditions and the development of the malarial parasite is at the present time so complete, thanks to the work of the above-mentioned Italian authors, that a physician familiar with the morphology of the parasites is able, by examining the blood, not only to recognize the presence of malaria, but also to determine the form, type, the clinical course of the attack, and to foretell the time of occurrence of the paroxysms. We shall refer to this later.

Two other kinds of parasites have been observed in the blood in malaria—the so-called *crescents*, of the estivo-autumnal type of the disease, and *flagellate bodies*.

¹ Jul. Mannaberg, *Die Malariaparasiten*, Wien, 1893, and *Malaria* volume of Nothnagel's System.

² L. Reinhardt, *Die Malaria und deren Bekämpfung nach dem Ergebnissen der neuesten Forschung*, Würzburg, A. Stuber, 1905.

³ *Zeit. f. Hyg.*, 1899, vol. xxxii.

Figs. 25 to 27, Pl. 7, and No. 38, Fig. 3, Pl. 5 represent types of the crescent series, which are peculiar to the malignant (tropic) form of malaria. They differ in shape from the ordinary plasmodia, and possess a double capsule. The crescents (Figs. 25 to 27, Pl. 7, and Fig. 3, No. 38, Pl. 5) develop in the interior of the red blood-corpuscles, as indicated by the remnant of the adhering hemoglobin margin frequently seen attached to them. Elongated cigar-shaped and spheric formations (ovals and spheres of the crescentic series, Pl. 7, Figs. 25 to 27) develop from the crescents by changes in shape slowly enough to be observed under the microscope. These forms do not possess any ameboid motion proper. Mannaberg (*loc. cit.*) believed that he had proved that the crescents are permanent bodies formed by approximation and fusion of two plasmodia in the interior of the red blood-cells, and that they are therefore a kind of copulation type—a so-called syzygy formation. The crescents may divide into their component parts by subsequent segmentation. This idea has not, however, been accepted by other observers. The modern view will be referred to below.

The flagellate bodies are found in all types of malaria (Pl. 7, Figs. 10 and 17). Under the microscope they may be seen to develop from adult plasmodia which have destroyed their blood-corpuscles and have not merulated (Figs. 9 and 15, Pl. 7), and again from the spheres of the crescent series (Figs. 25 and 27, Pl. 7). These flagella suddenly appear at the margin of the parasite; they move very quickly and lash the surrounding blood-corpuscles without, as a rule, inducing active locomotion in the parasite itself. Every once in a while individual flagella will tear themselves off and move about with great rapidity in the field. Their biologic significance will be discussed later.

Unstained blood-preparations may be employed to detect the malarial parasites. They should be especially thin (p. 770 et seq.), so that the individual blood-corpuscles may not overlap nor stick together and form rouleaux. The preparations are best examined with an oil-immersion, Abbé's condenser, and a half-open iris diaphragm. The pigmented forms, the crescents, and the flagellate types can be very easily detected, but the hyaline forms are not so easily differentiated from the endoglobular types of degeneration which are seen in fresh preparations after the lapse of a little time, and which were formerly considered vacuoles. (See p. 782 and Pl. 7, 18 to 22.) Differences of light refraction, however, cause a more sharply outlined contour in the latter than in the plasmodia. Ameboid motion is common to both. (See p. 783.) Doubtful cases can be decided by examining stained preparations (see below). Where so few plasmodia occur as to be difficult to demonstrate, Türk recommends diluting the blood ten times with a $\frac{1}{4}$ per cent. solution of acetic acid, just as for counting plasmodia and leukocytes (see below), and searching for pigmented forms, which are usually quickly found with lower powers of the microscope. The leukocytes and plasmodia will be preserved and the red blood-corpuscles destroyed, or, at any rate, be rendered invisible.

Malarial blood should be stained as indicated on p. 772 et seq. Staining is especially advisable in demonstrating the tropic forms of the parasite, which, on account of their small content of pigment, are often difficult to detect in any other way. Fixation may be accomplished in various ways instead of by heating, by allowing the slides to remain for five minutes in absolute alcohol.

The simplest stain is borax methylene-blue, first recommended by the author, and best employed after Manson's method: 2 gm. methylene-blue are dissolved in 100 cc. of boiling 5 per cent. borax solution. For use this stock solution is diluted in a test-tube with sufficient water to make it just transparent. The preparations are fixed by heat or alcohol for twenty minutes, stained for ten to fifteen seconds, and then washed in water. Ordinary methylene-blue also gives good results.

The endoglobular degeneration spots remain colorless, but the plasmodia stain well with methylene-blue, and show a characteristic structure, namely, an unstained nucleus and sometimes a stained nucleolus. The structure, especially the stained nucleolus, enables us to distinguish blood-plates and granular debris of the blood from the young merulation forms of malarial parasites. The blood-plates show no nucleus and are devoid of structure; the red cells are greenish, and the nuclei of the leukocytes intense blue.

Even Jenner's stain without previous fixation gives good results.

For the recognition of the finer structures of the malarial parasites Mannaberg's, Koch's, and Romanowsky's stains are to be preferred. Nowadays they are always employed according to Giemsa's or Leishman's technic. (See pp. 779, 780 et seq.) With this stain the protoplasm of the parasite appears blue, the chromatin an intense red, the normal elements of the blood as described on p. 779 et seq. The red granule

FIGS. 18, 19, 20.—Ring-like and cross-like hyaline forms; 21, 22, pigmented forms; 23, 24, segmenting forms; 25, 26, 27, crescents.

of chromatin, which is eccentrically placed in the unstained nucleus of the immature ring-form, is particularly characteristic (seal-ring form, Pl. 5, Fig. 3, No. 37). The young merulation forms may be sharply differentiated from platelets by their conspicuous red chromatin granules. (See Pl. 5, Fig. 3, No. 39.)

It should be noted that in stained smears the immature plasmodia which are as yet in the red cells are almost always ring-forms (Pl. 7, Figs. 18 and 20, Pl. 5, Fig. 3, No. 37).

To find malarial plasmodia quickly when they are but sparingly present, R. Ruge¹ recommends employing a thick layer of blood from which the hemoglobin has been removed before staining, in a similar manner to the method described upon p. 812. A cover-glass is thickly smeared with blood, dried, and then laid with the smeared surface down in a watch-glass containing 2 per cent. formaldehyd and a $\frac{1}{2}$ to 1 per cent. acetic acid. A few minutes suffice to fix the specimen and also to extract its hemoglobin. It is now stained with methylene-blue in the ordinary manner, and the plasmodia may be readily found, even though there be a number of layers of erythrocytes. This procedure has the advantage of employing more than twenty times the volume of blood utilized in the usual cover-glass smear. Ruge admits, however, that there is always a greater or less amount of precipitate, which an inexperienced observer might differentiate from plasmodia with difficulty. He also calls attention to the fact that the characteristic ring-forms of the young malarial plasmodia (p. 818) are beautifully shown by this procedure.

Counting the plasmodia gives more or less information as to the severity of a malarial infection. Türk counts them in the same way as leukocytes (p. 757 et seq.), in a $\frac{1}{2}$ per cent. solution of acetic acid, a method available only for the pigmented forms. The time of counting should, therefore, be immediately before the paroxysm, e. g., in tertian fever, the evening before the day of fever. Türk's figures vary between 6700 and 16,800 per cubic millimeter.

The *diagnostic significance* of malarial parasites in the blood is absolute. The unmistakable presence of a single parasite is sufficient for a diagnosis of malaria (the pigmented forms and the crescents cannot be mistaken). Negative results are not so certain, because many cases of malaria require a long search before a single parasite is seen. The blood should be examined both during and between the attacks. Even the most expert investigators have been sometimes compelled to make the diagnosis of malaria without finding the parasite. In these cases the parasites are either very few in number or else are supposed to develop in the tissues rather than in the blood. An inexperienced examiner should always mistrust a negative result and repeat his search. In case of repeated negative blood-examination, suspicion should be directed to the presence of one or more diseases, which are easily confounded with malaria clinically, e. g., acute sepsis, irregular cholelithiasis, ulcerative endocarditis, etc.

The blood of severe malaria shows, in addition, the characteristics of anemic blood. The diminution of hemoglobin and of the number of red cells is explained by the destruction of the latter by the parasites. Poikilocytosis is by no means uncommon; even normoblasts and megaloblasts have been observed. There is usually no pronounced permanent leukocytosis, but rather a leukopenia. (See p. 802.) The presence of pigment in the white blood-corpuscles or pigment floating free in the blood is of considerable diagnostic importance if the parasites cannot be found. (See pp. 802 and 811.) The red blood-cells which are invaded by the parasites may be altered in various ways. The ordinary types usually decolorize the cells gradually, until finally all that is left is an indistinct stroma surrounding the parasite. The blood-corpuscles may be considerably enlarged by the tertian parasites, which differ from the quartan variety in this respect (Pl. 7, Figs. 12 to 14). In the malignant types the infected blood-corpuscles shrink and become darker, and, according to Mannaberg, resemble the color of old brass (brassy bodies). In regard to the occurrence of the pernicious anemia blood-picture in malaria, see p. 802.

Differentiation of the Varieties of Plasmodia.—The majority of investigators have concluded that the various forms of malarial parasites found in the blood represent various developmental phases, not only of the same, but also of different, species. Each type of malaria which is characterized clinically and endemiologically represents a separate species of parasites with a definite cycle of development. The reasons for these views may be found in Mannaberg's monograph. He describes the following five species of parasites:

1. The parasites of quartan fever.
2. The parasites of the common tertian fever.

¹ See Mannaberg in Malaria volume of Nothnagel's System.

- | | |
|---------------------------------------|-----------------------------------|
| 3. Pigmented quotidian parasites. | } Malignant types with crescents. |
| 4. Non-pigmented quotidian parasites. | |
| 5. Malignant tertian parasites. | |

Those of 3, 4, and 5 are malignant varieties with crescents, which probably explains the difficulty with which these cases are influenced by quinin.

R. Koch, on the other hand, considers these three groups of parasites as one species, which is to blame for the malignant summer fevers (estivo-autumnal) of southern Europe, especially of Italy and of the tropics. Koch, therefore, distinguishes only the parasites of *quartan*, *tertian*, and *tropic* fever. He shows that a fresh infection of the parasite of tropic fever always produces attacks of a pronounced tertian type (corresponding to the term 5, malignant tertian parasites). When the disease has persisted for some time and the natural course has been more or less influenced by treatment with quinin, there may develop from the tertian type either a quotidian type, an irregularly remitting, or a continued fever. According to this view there is no true quotidian parasite. Koch's simplified classification is based more or less upon his view that the difference in the pigment which gives rise to the distinction between the so-called pigmented and non-pigmented quotidian parasites (see above) is an artificial condition depending upon the method of preparation. When dry preparations were made skilfully and rapidly, he found that the young parasites of tropic fever were, as a rule, without pigment or had only very fine granules, and, at any rate, were free from clumped pigment, even when the fine pigment lent a brownish diffuse hue; clumped pigment was found only when the parasite underwent subdivision or death. If a wet preparation was allowed to stand for any length of time, clumped pigment was apt to develop. Koch, therefore, maintains that the only correct method of examination is by employing properly dried smears.

For determining the various varieties, Koch lays special stress upon the size of the parasite and the presence of crescents so characteristic of the tropic fever. The fully developed malignant parasite is barely one-half the size of the tertian or quartan, and it retains the ring-form much longer. Koch makes the following statements in regard to this matter: The young ring-form parasites of tertian and quartan fever have a diameter of about one-quarter to one-third that of the red blood-cells. In size and shape they resemble the fully developed parasite of tropic malaria so completely that they cannot be differentiated. But, as a rule, in tertian and quartan fever, in addition to the small ring-forms, scattered large pigmented parasites are found which may be differentiated from developed malignant parasites by their greater size. If the large mature forms should be absent, the determination of the body temperature at the time of examination will furnish sufficient explanation of the significance of the preparation. If the temperature be low and the paroxysm is over, the parasites must have completed their cycle of development. The small types found must, therefore, represent the fully developed smaller parasites of the tropic malaria. If, on the other hand, the temperature be high and the patient be in the early stages of a paroxysm, then these small ring-forms must be young parasites of the tertian and quartan groups which have not yet reached their full size.

The variations of merulation also serve to distinguish the individual varieties. This is seen in Plate 7 better than it can be described. The regular sun-flower segmentation forms of the quartan (Figs. 5, 6, and 7) may be differentiated from the irregularly segmenting tertian parasites (Fig. 16). Another rather characteristic appearance of the quartan parasite during its development in the afebrile stage is its band-like form stretching from one edge of the red cell to the other.

It is of some clinical interest to be able to predict the time of a paroxysm merely from the period of merulation (Figs. 5 to 8 and 16). It usually takes place three to five hours after the merulation forms have appeared.

The *crescents* are said to be formed in the blood eight days after infection. If these persist in the blood along with the other forms of the parasite, after cessation of fever, recurrences may be expected. There is ordinarily no fever when crescent forms only are present. The significance of the so-called *flagellate forms* has recently been explained.

Sexual Cycles of Development—Significance of the Flagellate Forms and Crescents.—The investigations of Ross, MacCullum, Sakharoff, Koch, *et al.*, with the hemopsporidia species *halteridium* and *proteosoma*, which occur in birds' blood and which are closely related to the malarial parasites of human blood, have shown that, besides the endogenic cycle of development culminating in merulation, there is a second sexual cycle of development. Koch divides this into the following stages: 1. Separation of the parasite from the red blood-corpuscle. Differentiation into

male and female elements. The male gametes (microgametes) differ from the female gametes (macrogametes) by their greater chromatin content and usually by their smaller size. The thread-like formations which were formerly considered flagella develop from the interior of the male. They separate, propel themselves independently, and play the part of spermatozoa. 2. Fecundation by penetration of the spermatozoa into the female plasmodia. This takes place in the stomach of a mosquito (intermediate host) which has sucked the blood from some infected bird. 3. Change of the impregnated female parasites into worm-shaped bodies. 4. Penetration of the stomach-wall of the mosquito by the latter and their change to coccidia-like spheres. 5. Formation of sickle-shaped bodies (spores) in these spheres. 6. Deposit of these, fully developed and liberated, in the veneno-salivary glands and perhaps in the other organs of the mosquito. 7. Transmission of young parasites again to birds by fresh bites of the mosquito.

It has been shown that these biologic facts are also true for the parasites of human malaria, especially since the transmission of the disease by mosquito bites, an old and popular belief, has recently been definitely proved experimentally.

It may, at the present time, be considered proved that the crescents represent simply the first stage of the gametes (macro- and microgametes, i. e., female and male forms of the tropical estivo-autumnal), malarial parasite. These in the course of development lose their double form, assume an oval and then a spheric shape, and from this moment are divided into male and female gametes (micro- and macrogametes). The male gametes of this form put forth flagella-like spermatozoa analogous to the gametes of the non-tropical forms. Whether or not, in spite of this conception of the insignificance of the crescents, Mannaberg's view of their origin (see above) is correct is yet undecided. The two theories are not absolutely inconsistent.

It is of considerable pathologic interest to know that the action of quinin results in necrosis of the parasite. This may be recognized in stained preparations by the disappearance of the nucleus. Very young parasites are more susceptible to its action, which accounts for the rule that it is best to give quinin three or four hours before an attack is expected. The crescents are almost immune to the direct action of quinin, as shown by microscopic examination, so that the action of repeated doses of quinin in malignant types resembles more or less a process of fractional sterilization. The crescents themselves are not disturbed, but the plasmodia developing from them are killed by the repeated doses. In exceptional cases, however, the crescents are not so resistant.

TRYPANOSOMES IN THE BLOOD

The human trypanosome diseases which have only recently been exhaustively studied are becoming of greater practical importance on account of their increasing spread throughout Africa. They arise from an infection of the body, and especially the blood, by the *Trypanosoma Gambiensi*, a protozoön belonging to the group *Flagellata* or *Mastigophora*. (See Fig. 312.) The trypanosome is spindle-shaped, with a rounded anterior and a tapering posterior extremity. In the granular protoplasm are a rather large nucleus and a vacuole, the latter at the forward end. A long flagellum which arises from a collection of chromatin at the forward end of the cell, turns backward in the direction of the cell-body, with which it is connected by a so-called undulating membrane, and at the hinder end forms a free thread. By Giemsa's stain, the flagellum (including the edge of the undulating membrane), the nucleus, and the collection of chromatin at the anterior end are colored red while the remaining parts are a violet blue. The parasites can be recognized even in fresh preparations if pressure on the cover-slip be avoided (for they are very fragile). To do so it is best to rim the cover-slip with a thin layer of paraffin. In such preparations the parasites move in odd spiral paths among the red cells, to which they impart very slight motion. They can be recognized by low-power lenses since they are

Fig. 312.—*Trypanosoma Gambiensi* in the blood (after Guiart and Grimbert).

15 to 30 μ long (3 to 6 times as long as a red cell) and 1.4 to 2.5 μ broad. The smears must be made very thin, and very gently. The use of a little piece of gold-beater's skin held in a pair of forceps is recommended for making the smears. The slide method may also be recommended as very satisfactory. Stäubli's sedimentation method for demonstrating trichina embryos in the blood (see p. 823) may be mentioned in this connection. The vapor from a mixture of osmic and acetic acids is recommended for fixation, but immersion in a mixture of 10 parts of commercial formalin and 90 parts of absolute alcohol gives good results. Giemsa's and Leishman's stains are best. (See p. 779 et seq.) Besides the perfect organisms, degeneration forms are also found. These are ameboid, pear-shaped, or spheric structures without flagella. The parasites are sometimes present in the blood in very small numbers and may even disappear from it, so that occasionally puncture of the cervical lymph-nodes, in the tissue juices of which they are numerous, is necessary. They may disappear from the blood for long periods and then reappear in great numbers. Guiart and Grimbert¹ recommend making smears from the upper layers of the sediment obtained by mixing the blood with a 1 per cent. solution of sodium citrate (to prevent coagulation) and centrifuging repeatedly. Possibly the Stäbelin-Nöggerath method, used to demonstrate spirochætæ, could be used in searching for trypanosomes. The parasites would then be concentrated in a small amount of plasma. In severe cases the organisms are found in the cerebrospinal fluid as well as in the blood and lymph-nodes. Trypanosomiasis runs a chronic course, with an irregular fever, cachexia, localized edema of the face, trunk, and legs, and enlargement of the lymph-nodes and spleen. The special form, called *sleeping sickness*, which cannot be differentiated etiologically from the others, seems to be in some way connected with the presence of trypanosomes (frequently together with streptococci) in the cerebrospinal fluid. The sleeping sickness is to some extent the terminal stage of trypanosomiasis. The parasites are carried by a kind of biting fly, *Glossina palpalis*. *Trypanosoma Gambiense*, the variety occurring in man, can hardly be distinguished from certain other varieties observed in animals. It belongs, according to Koch, to a group of trypanosomes which have not phylogenetically been divided into definite species, and which vary in virulence and morphology in different hosts. Several different varieties occur in man as well as in animals. The species occurring in man cannot be sharply differentiated from those of the tsetse disease (*nagana*) of horses and cattle in Africa. There is, however, a group of distinct species which Koch calls permanent varieties and which have a strong affinity for particular animals, but which do not occur in man. To these species belong the trypanosomes found in rats; those of surra of horses, asses, and camels, in India and the Philippines; those of Mal de Caderas of the Equidæ of South America; and those of the dourine of the horse in Algiers, North America, and the valley of the Danube. (For an exhaustive discussion of trypanosomes see Koch, Deut. med. Woch., 1904, No. 47, and for a more recent review of the forms occurring in man see Martin Meyers, Ergebn. d. inn. Med., und Kinderheilk., 1908, vol. ii.)

PIROPLASMATA IN THE BLOOD

The piroplasmata are peculiar protozoöns which owe their name to the pear shape of certain of their developmental forms. As parasites of the red cells of many animals, they play an important rôle. They are the cause of Texas fever (transmitted by ticks) and of the coast fever of cattle as well as other important animal diseases of tropic and subtropic countries. Neither their presence in human blood nor their significance as a cause of disease in man has been demonstrated. Purple fever, a peculiar disease endemic in the Rocky Mountains, was formerly ascribed to piroplasmata, but more recent researches point to a spirocheta as the cause. A febrile disease, called tropic splenomegaly, first described by Leishman in India, but also observed in China and Japan, was thought to be due to a kind of piroplasma, the Leishman-Donovan bodies. Recent studies of Kossel, Weber, Schaudinn, and Rogers have shown that this is a pear-shaped descendant of the trypanosome. Until further evidence comes to hand piroplasmata should not be regarded as human parasites.

WORM EMBRYOS IN THE BLOOD

FILARIA AND TRICHINA

Of the two helminthes inhabiting the human blood in the tropics, *Distomum hæmatobium* (*Bilharzia hæmatobia*) and *Filaria sanguinis*, only the latter is of

¹ Diagnostic chimique microscopique, etc., Paris, 1906.

diagnostic importance in blood-examinations. The blood of patients infected with filaria (tropic chyluria) contains numerous small, thread-like worms, the filaria embryos, 0.21 to 0.36 mm. long and 0.004 to 0.0075 mm. broad (Figs. 313 and 272, p. 694). For the other blood-findings, see p. 840. Recently different varieties of *Filaria sanguinis* have been distinguished, of which *Filaria Bancrofti* (nocturna) is the most frequent (Fig. 313). This organism appears in the blood only at night. *Filaria diurna*, whose embryo appears only in the daytime, and *Filaria perstans*, whose embryos are present day and night, have been described. In addition, *Filaria gigas*, *Filaria Demarquai*, *Filaria Megalhäesi*, *Filaria loa* and *Filaria Ozzardi* may be mentioned.

According to Stäubli's experimental studies, the demonstration of trichina embryos in the blood will have to be considered in the diagnosis of *trichinosis* in the future, although to the best of the author's knowledge they have not yet been demonstrated in man. [Herrick and Janeway¹ and Mercur and Barrach² report the demonstration of trichina embryos in two cases; 10 cc. of blood were withdrawn from a vein in the arm and Stäubli's method (see below) was used in both instances. The organisms were found in the fresh sediment. All stained smears, however, proved negative.—Ed.] Stäubli found the trichina embryos in the blood of guinea-pigs seven days after the ingestion of infected meat. He used the following method of examination: All the blood that can be obtained from the animal's heart³ is immediately mixed with a large volume (20 to 30 cc.) of 3 per cent. acetic acid. This destroys the red cells without injuring the parasites. The mixture is centrifuged and examined with the low power (Zeiss A with ocular No. 3), either directly or after staining smears dried by gentle heat. Jenner's stain is satisfactory. The embryos stain an intense blue with a pale red border. They are about 0.08 mm. long and not quite so thick as the diameter of a red cell. (See Fig. 224 c, p. 524.) Stäubli thinks that this method can be used in demonstrating any parasites in the blood (*Filaria*, *Trypanosoma*, etc.). Indeed, Nöggerath and Stähelin have used a modified form of it to demonstrate *Spirochæta pallida*. (See p. 816.) Stäubli pictures a low magnification of a smear obtained by this method.

• Fig. 313.—*Filaria Bancrofti* (nocturna) (after Emerson).

CONDITION OF THE BLOOD IN THE MOST IMPORTANT BLOOD-DISEASES

THE ANEMIAS

The condition ordinarily called *anemia* should more correctly be termed *oligochromemia*. Either merely the quantity of hemoglobin in the blood may be decreased, or the number of erythrocytes may also be simultaneously diminished. Such differences in the individual anemias are shown by the magnitude of the hemoglobin quotient or color index. (See p. 765 et seq.) In anemia from hemorrhage and sometimes, according to recent researches (see p. 734), even in pernicious anemia, there is, on the contrary, a diminution in the mass of blood. In the former case this is, however, only temporary. In all anemias undeveloped (nucleated) erythrocytes may be present in the blood, as the result either of a disturbed or of an incomplete development. The subdivisions of anemia vary considerably. The following arrangement would seem to correspond best to the actual conditions.

The previously accepted division of anemias into primary and secondary is no longer possible, for a constantly increasing number of so-called primary anemias, to which pernicious anemia belongs, are being proved to be secondary. The conception of a primary disease is highly unscientific, for even the so-called primary diseases are the consequence of some preëxisting cause, which we either do not know or illogically ignore in our terminology. In regard to anemia in infectious diseases, see p. 798.

¹ Archives of Int. Med., 1909, vol. iii, p. 263.

² Ibid., 1910, vol. v, p. 530.

³ It has yet to be proved whether or not venous blood, which must be used in man, is satisfactory, since it is quite conceivable that the embryos do not pass into the general circulation, but immediately collect in the muscles. (See Ed. note above.)

Chlorosis.—The chief characteristic of the blood in chlorosis is a diminution in the amount of hemoglobin. This is not infrequently as low as 20 or even 15 per cent. According to Plesch and Oerum,¹ the mass of blood seems usually to be increased. Though there may be a normal red cell count, the number of red blood-corpuscles is also usually diminished, and sometimes very considerably (1,500,000); but it is more or less characteristic that the diminution of hemoglobin in chlorosis is more marked than the diminution of the number of red cells.

The *color index* (hemoglobin quotient or value, p. 765 et seq.) is therefore less than 1. The pallor of an individual blood-corpuscle may sometimes be recognized microscopically. (See p. 783.) In chlorosis the volume index (volume quotient) is usually diminished (see p. 785 et seq.) approximately in proportion to the severity of the disease. The individual red cells vary in size. The number of small forms varies with the volume index. However, occasionally abnormally large cells are found which differ from megalocytes of pernicious anemia by their less intense stain. (See p. 785.) Severe cases of chlorosis exhibit poikilocytes, microcytes, nucleated red cells (normoblasts and even, in the most severe cases, megaloblasts), and the degenerated forms of red blood-cells described by Maragliano (p. 782 and Pl. 7, 24 to 28). Granular basophilic and polychromatophilic changes in the erythrocytes may be present. (See p. 784 et seq.) The number of white corpuscles and of blood-platelets is usually within normal figures. Muir, as well as Hanot and Matthieux, found an increase in the blood-platelets (350,000 to 400,000). This coincides with the tendency of chlorotic patients to the formation of thrombi. The differential count of the leukocytes is normal. During convalescence Nägeli found a high leukocyte count with an increase in the eosinophiles. Neusser considers such an increase of favorable prognosis. A diagnosis of chlorosis cannot always be made from an examination of the blood alone, as in many cases it depends considerably upon the clinical picture. Chlorosis is a disease occurring during the period of development, especially in women, and is probably to be explained by the fact that the amount of blood formed is not sufficient for the demands of the growing organism.²

The urine of chlorotics is pale and contains but little urobilin. This favors the theory just given, and indicates that the destruction of red blood-corpuscles is limited, for in some other types of anemia, especially in so-called *pernicious anemia*, the increased destruction of red cells is manifested clinically in a dark urine, which contains a good deal of urobilin. The patient is usually well nourished, and may even be increased in weight, and this is responsible for the peculiar appearance of many cases of chlorosis. Von Noorden demonstrated that this abundance of fat in chlorotics is not due to the diminution of the oxygen content of the organism from deficiency in the hemoglobin of the blood, but to the relatively diminished exercise enforced upon the patient by the disease.

The following remarks refer to the clinical picture which the author has termed *masked (larval) chlorosis*.³ The consideration of this as a clinical entity is based

¹ Plesch, Cong. f. inn. Med., 1907, reference in Berlin. klin. Woch., 1907, No. 23, p. 731; Oerum, Arch. f. klin. Med., 1908, vol. xciii, p. 4.

² The question whether chlorosis occurs in males also is, of course, pertinent only if the condition "of the female sex" be omitted from the definition. The extraordinary preponderance of females suffering from this disorder during puberty argues for the separation of the disease from analogous anemias in males, and for the theory that chlorosis is in some measure a secondary pathologic condition of the female sex. It must be associated with the peculiarities of the female sex. Apparently, disturbances somewhere in the generative organs inhibit the stimuli which affect the blood-forming organs, upon which is dependent the normal blood-formation of the female. The conception that blood-formation is intimately connected with the female sexual organs has much in its favor, as it is reasonable to assume that the female body, which loses blood during menstruation, a process peculiar to the sex, must have an adaptive mechanism in the genitalia which serves to stimulate blood-formation. The supposition also explains how even later, after development is complete, conditions may arise which in all respects except the age of the patients correspond to chlorosis and indeed are frequently to be regarded (exclusive of recrudescence of chlorosis) as disturbances of genital functions. In such a patient the history of a previous chlorosis in youth frequently argues for such an assumption, as does also the introduction of the relapse by amenorrhea, just as is observed at the onset of chlorosis.

³ See Dubnikoff, Klinische Untersuchung über Eisenwirkung und larvierte Chlorosis, I. A. D., Bern, 1908, and Seiler, Ueber larvierte Chlorosis, Correspondenzbl. f. Schw. Aerzte, 1908.

upon the fact that there are patients who suffer from the general symptoms of chlorosis in whom the hemoglobin percentage is either normal or only slightly below normal. Thus the hemoglobin may be 88 to 94 per cent. (corrected),¹ which, although found in normal individuals, is to be considered an abnormally low value in the patient, since the administration of iron influences the general symptoms favorably and increases the hemoglobin. On the other hand, there are patients with the same hemoglobin percentage and other symptoms of chlorosis who do not react at all to iron, and in whom, as a rule, further observation and study lead to the diagnosis of another malady, especially incipient tuberculosis or neurasthenia. It follows from this that in these cases the study of the blood alone does not establish the diagnosis of chlorosis, but that besides excluding other diseases, it is necessary to make the therapeutic test. The author would discourage the tendency to regard hemoglobin estimations as superfluous and would advise against the administration of iron in all pale patients, since only a small minority of the patients without a marked decrease in hemoglobin derive any benefit from iron, and by the use of hemoglobin estimations, one has a far surer basis for his therapy than without.

This conception of masked chlorosis advanced by the author should not be confused with that of pseudochlorosis advanced by Laache, to which it is in a way opposed. In contrasting such cases with chlorosis Laache has in mind anemic looking men, in whom the pallor is caused by "previous processes which cannot be more accurately designated" without any change in the hemoglobin percentage. The name pseudochlorosis was suggested to him by the name pseudoanæmia spastica, applied to angiospastic conditions. Nor is masked chlorosis to be identified with the pseudoanemia of Strauss² since he includes the pallor of perfectly healthy as well as that of really sick individuals in whom there is no diminution of hemoglobin. In opposition to these ideas of pseudochlorosis and pseudoanemia the author would emphasize that masked chlorosis, though difficult to diagnose, is an actual clinical entity and in no sense a false chlorosis.

Simple So-called Primary Anemia.—Under this term we may include all cases except *chlorosis* and so-called *pernicious anemia*, where there is a diminution of the hemoglobin or red cells, either of one or both at the same time, and where no other disease is present which can cause the conditions. Simple primary anemia, like chlorosis, can be considered a disease of the blood-forming organs; it differs from chlorosis only in that it does not affect growing individuals, and is not, therefore, a disease of development. The fact that the condition of the blood in simple primary anemia is identical with that of chlorosis supports this view.

The so-called *masculine chlorosis* of males during puberty may well belong to this group. The much greater frequency of chlorosis in women argues for a separation of these cases from chlorosis proper (see p. 824), for it shows that the latter is, to a certain degree, a pathologic sexual characteristic peculiar to females. The fact that the simple so-called primary anemias of males are not connected with puberty to the same degree as is chlorosis, and that they cannot therefore be considered peculiar to this period of life, is a further argument for the separation.

Infantile Pseudoleukemic Anemia (v. Jaksch-Hayem).—This term is applied to a peculiar anemia, sometimes congenital, but usually occurring in earliest infancy, frequently, indeed, in the first month and persisting through the first year. It resembles true pernicious anemia in that megalocytes and megaloblasts are found, but differs from it in the occurrence of a leukocytosis, partly polynuclear, partly lymphocytic. It has no definite etiology. The cause has been ascribed to digestive disturbances, rachitis, syphilis, and other diseases. The red cells may be reduced to 1,000,000; the hemoglobin, to 20 per cent. The color-index may be greater or less than 1. Megalocytes, microcytes, poikilocytosis, anisocytosis, polychromatophilia, and basophilic degeneration of the red cells may be found. Megaloblasts and normoblasts are present, the latter usually in great numbers. The leukocytosis may reach 20,000 or more. It is in most cases decidedly polynucleophilic; in others, on the contrary, it is a pure lymphocytosis. At times myelocytes are found in great numbers, so that confusion with myeloid leukemia is conceivable, although the latter never, or at any rate very rarely, occurs at this age. (See p. 835 et seq.) The eosinophiles may be either increased or decreased in numbers. The spleen is usually large. The bone-marrow is dark red.³

¹ In regard to the meaning of corrected percentages see p. 753.

² Berlin. klin. Woch., 1907, No. 19.

³ For the pathologic anatomy see Nägeli, Blutkrankheiten und Blutdiagnostik, p. 293, et seq.

Besides the cases presenting the above typical clinical picture, many cases of secondary anemia occur which resemble infantile pseudoleukemic anemia more or less closely. It is, therefore, quite right to consider these peculiar symptoms of infantile anemias (especially the tendency to leukocytosis) as the expression of the peculiar reactive ability of the immature blood-forming organs and not of a specific disease.

So-called Pernicious Anemia (see Pl. 7, Fig. 1).—As indicated by its name, this disease is malignant, and implies an unfavorable prognosis. This view, however, does not entirely explain the situation, for the severity of the symptoms is a relative affair, and undoubtedly many cases of so-called pernicious anemia have recovered. Only the so-called idiopathic or cryptogenetic (Biermer) form of pernicious anemia is truly incurable; yet even this form does not differ sharply either in the blood-picture or (at least according to the author's theory, introduced below) even in the etiology from cases where pernicious anemia is secondary to a curable malady. The characteristic of incurability alone is not sufficient to differentiate it from other anemias which may also be incurable. Indeed, it would be more suitable to seek for the essential differences between pernicious anemia and chlorosis or the so-called simple anemias not only in signs of defective blood formation, but also in those of abnormal destruction of blood-corpuscles, which latter does not concern these other anemias. The only sharp definition of pernicious anemia (in which, as we express it, the bone-marrow reverts to the embryonic type) is based on the changes in the morphology of the blood. The special features are the occurrence of megalocytes, the high color-index, and, in the majority of cases, the appearances of megaloblasts. The destructibility of red blood-corpuscles in pernicious anemia is usually indicated clinically by the marked poikilocytosis, the presence of basophilic degeneration of the red cells, and the presence of urobilinuria and icterus. Anatomically, there is a deposit of iron in the liver and kidneys, as shown by Quincke. The basophilic stippling and the polychromatophilic changes in the red cells (see p. 783 et seq.) which occur so frequently in this disease should no longer, as formerly, be considered degenerative, but rather regenerative, changes. For a definition of the disease see Nägeli's excellent review (*Blutkrankheiten und Blutdiagnostik*, 1908, p. 252).

The number of red cells is usually considerably more diminished in pernicious anemia than in chlorosis and simple primary anemia, and sometimes to a very marked degree. In a case of Quincke's the red cell count was 143,000 per c.mm. This diminution is generally more marked than the reduction of the hemoglobin, hence the color-index is above 1. This is chiefly due to the preponderance of abnormally large erythrocytes, as is expressed by the volume index (see p. 785), and is evident in the stained smears. In addition, at least a part of the smaller red cells are evidently abnormally rich in hemoglobin. (See, however, Capp's assertion, p. 786, that the red cells are normally saturated with hemoglobin.) The corrected hemoglobin percentage must be used in determining the color-index (p. 753 et seq.).

The macrocytes, so characteristic of pernicious anemia, may measure 12 μ or more in diameter. Normal sized red cells, moderately enlarged megalocytes, and microcytes are included. Microcytes are, however, less characteristic than megalocytes. Abnormally pale as well as abnormally red cells are present. It is usually possible to find stippled cells (erythrocytes with basophile granules), although in very small numbers; and red cells with polychromatophilic changes are more or less abundant. The presence of megaloblasts in the blood, however, is specially characteristic of pernicious anemia. They are usually very scanty and require patient searching. They are found only exceptionally in large numbers, and then only in the agony of death.

They may be absent for long periods. They sometimes show destruction of the nucleus, and rarely mitoses. The author has frequently observed the development of megaloblasts, as the lesion in the blood became more severe, after a positive diagnosis of pernicious anemia had been made from the other symptoms. The presence of megaloblasts should not, therefore, be considered absolutely necessary for the establishment of a diagnosis; indeed, megaloblasts are lacking in the most severe form (the so-called *aplastic* pernicious anemia, see below), in which the bone-marrow remains yellow in color and shows no sign of regeneration. This, however, is in itself by no means diagnostic of the aplastic nature of the disease. Much more suggestive of this condition are a very marked leukopenia and other evidences of a lack of regenerative power, such as the absence of polychromatophilia, of basophile degeneration, and of normoblasts. In certain stages of pernicious anemia the latter occur in great numbers either alone or together with megaloblasts. During periods of improvement the megaloblasts are usually reduced in numbers and may be more or less completely replaced by normoblasts. During the temporary arrest of idiopathic

pernicious anemia effected by arsenic, all nucleated red cells gradually disappear. The same is true of the complete cure of certain other forms.

The number of leukocytes is usually diminished in pernicious anemia. As the function of the bone-marrow is diminished, this decrease is at the expense of the polynuclear leukocytes, so that the lymphocytes seem to be relatively increased. According to Ehrlich and Lazarus, they may constitute 62 per cent. of the total number. Strauss¹ regards the decrease of the polynuclear leukocytes as characteristic of true pernicious anemia, as compared with anemia following carcinoma, in which the percentage of the polynuclear cells is usually greater than that of the mononuclear, and in which there is frequently present a pronounced polynuclear leukocytosis. The latter peculiarity, however, is not always present in the anemia of carcinoma, and may sometimes be observed during a temporary improvement in pernicious anemia. In pernicious anemia the blood-plates are diminished in number.

The ordinary form of pernicious anemia is characterized by a peculiar reaction of the bone-marrow, manifested by a replacement of the fatty by a red marrow and by the embryonic type of blood-formation which, according to Nägeli, include the megalocytes, the high color-index, and the megaloblasts. Yet other cases occur in which this change from a fatty to an active marrow and the blood-picture resulting therefrom are lacking. These cases have been termed *aplastic pernicious anemia*. The aplasia can sometimes be recognized from the blood-picture by the absence of megaloblasts and normoblasts, the absence of polychromatophilia and basophile stippling of the red cells, sometimes by the absence of megalocytes and, finally, by an extraordinary decrease in the number of leukocytes. But, as stated above, the absence of megaloblasts alone is not sufficient to establish the aplastic character of the anemia.

The old supposition that the mass of blood is diminished in pernicious anemia, which was based on postmortem examination, has recently been confirmed by Kottmann's² direct estimations of the quantity of blood in the living subject. There are, however, clinical grounds for assuming that in some cases the disease may be complicated by hydremic plethora. Cases of the former class are apparently characterized by a recession of the hemic murmurs (since, owing to the smaller volume of blood, the current is slowed) and by the absence of marked cardiac dilatation; while those of the latter present signs of cardiac enlargement, loud hemic murmurs, venous hums, and frequently distention of the neck veins and subcutaneous edema.

Occurrence and Etiology of Pernicious Anemia.—After Biermer's³ original description of pernicious anemia and Quincke's⁴ exhaustive studies there was a tendency to regard this malady as an etiologic as well as a symptomatic entity. Recent studies, however, have shown that though, corresponding to Biermer's description, the disease, which can be defined to-day only by the blood morphology, may be apparently idiopathic or cryptogenetic, i. e., not preceded by any striking primary illness, and may occur to a certain degree as a specific disease; yet in many cases it has the character of a secondary malady. In the author's opinion the conclusive logical consequence of this fact is that pernicious anemia may, as yet, be considered only a symptom-complex. In his opinion the so-called cryptogenetic or idiopathic cases, and many, perhaps all, of the cases which are considered secondary, have a common and manifest pathogenesis in gastric achylia or marked hypochlorhydria, so that even the idiopathic cases should no longer be considered cryptogenetic. To support this theory, it is necessary to call to mind the occurrence of blood changes resembling those of pernicious anemia in diseases which are manifestly primary. The longest known is the so-called bothriocephalus anemia, which may be classed with analogous anemias due to *Tænia mediocanellata* and *Trichocephalus dispar*. Ankylostoma anemia seems to be due essentially to hemorrhage and does not belong to this group. The typical blood-picture of pernicious anemia (showing leukopenia, megaloblasts, and other evidences of the embryonic type of blood-formation) does occur, although rarely, in individual cases of gastric carcinoma, although it must, of course, be granted that in the majority of cases of the latter disease, even if megaloblasts be present, the blood-picture differs from that of pernicious anemia in the occurrence of leukocytosis. Nägeli has found the practically typical picture of pernicious anemia in

¹ Strauss and Rohnstein, *Die Blutzusammensetzung in den verschiedenen Anämien*, Berlin, 1901.

² Kottmann, *Ueber die Viscosität des Blutes*, *Correspondenzbl. f. Schweiz. Aerzte*, 1907, No. 4.

⁴ *Deut. Arch. f. klin. Med.*, vol. xx, xxv, and xxvii.

the puerperium, so that Biermer's old idea of cryptogenicity is no longer tenable in many cases. Nägeli vouches for the occurrence of true pernicious anemia in syphilis, and the author has himself seen such a case to which no objection could be taken. In advanced malarial cachexia and in severe cases of sepsis the blood is sometimes typical of pernicious anemia. On the other hand, the assumption that the characteristic blood-picture may occur from repeated hemorrhages, from malnutrition, and in the terminal stages of severe and protracted chlorosis should be discredited. The alleged occurrence of pernicious anemia resulting from chronic nephritis (French writers) is more likely a combination of two independent diseases. The diseases in which, on account of the more or less close resemblance of the blood-pictures to pernicious anemia, were formerly confused with it will be treated hereafter under differential diagnosis. Aside from the true or cryptogenetic pernicious anemia, the occurrence of the *typical* blood-pictures is limited to certain cases of syphilis, malaria, and intestinal parasites, to the puerperium, and to rare cases of gastric carcinoma and sepsis. Precisely in the most frequent and best known of these conditions, viz., the true or so-called cryptogenetic form, in the bothriocephalus anemia, and in the anemia due to certain gastric carcinomata is there a marked disturbance of the gastric chemistry, evidenced by more or less complete achylia. Older observers were struck by this, and to the author it seems important in explaining the condition and by no means accidental. Unfortunately, nothing certain is known about the gastric chemistry of the other forms. But since the secretion of hydrochloric acid is of such great importance in digestion, it is quite fair to assume that a disturbance of the same has some bearing on the etiology of pernicious anemia. If further study of the remaining cases shows that they are not connected with this functional gastric disturbance, other causes must be found for them. It has been suspected that the general nutritional disturbance depending upon the deranged digestion might give rise to the anemia, but the association of cause and effect was sought in the wrong direction. In order to make this theory harmonize with the facts that gastrectomy has no such effect, and that achylia has been observed without pernicious anemia, it was assumed that the accompanying atrophy of the intestinal mucosa, which was found at autopsy, was the essential cause, because no compensation was made for the gastric disturbance. But, aside from the fact that this finding was soon recognized as a postmortem change, such an explanation is inadmissible, because malnutrition is not known to cause pernicious anemia. There are many severe nutritional disturbances in which pernicious anemia never occurs; and, as a rule, the nutrition of patients with pernicious anemia is maintained for a long time. It was then thought that abnormal decomposition products were formed in the intestine, because of the lack of the HCl secretion, which products, through their toxicity, gave rise to pernicious anemia. But this supposition is purely hypothetical. After these attempts at explanation failed, the whole theory of the absence of HCl as a cause of pernicious anemia was rejected by most writers; or at best was kept in the background, but the simplest explanation of all did not occur to any one. It was thought that bothriocephalus anemia, least of all, could be explained by the theory, since studies of Shapiro¹ and Tallquist² had shown that the parasite excretes hemolytic substances which, of course, seemed at first glance to offer sufficient explanation for the anemia. So it came about that the noteworthy discovery of the lack of the hydrochloric acid secretion in the stomach was regarded merely as a concomitant symptom or a consequence of pernicious anemia and of no etiologic significance. The author's argument favoring the significance of the suppression of the acid secretion as a cause is as follows:

As a result of his studies on the therapeutic effect of iron, Quincke³ demonstrated that iron preparations given to animals are absorbed from the duodenum only, *i. e.*, exactly from the place where the intestinal contents are under the influence of the HCl of the gastric juice. He showed that iron could be easily demonstrated microchemically in the intestinal epithelium. The acid of the gastric juice manifestly serves to dissolve iron salts and hold them in solution. These, through the alkaline action of the bile and the pancreatic juice, are more or less completely precipitated. Quincke's studies seem to show that this is also true of iron in the food, for he found the reaction for iron in the duodenal mucosa after the ingestion of ordinary food. It may, of course, be objected to the supposition that the HCl of the gastric juice plays a part in the absorption of organic iron in the food, that this iron, which is almost all in combination with albumin, is either soluble in non-acid material or at least remains in solution. But, according to the recent physiologic studies of Abderhalden and Cohnheim, the albumin compounds are

¹ Zeit. f. klin. Med., 1888.

² Ibid., 1907, vol. lxi.

³ Cong. f. inn. Med., 1896, p. 290.

much more completely broken up in the stomach than was formerly supposed. In the intestine the cleavage is carried on still further. The author would recall in this connection the work of Cohnheim, who has shown that, under the combined influence of trypsin and erepsin, protein in the intestine is completely broken up to its end-products, i. e., into amino-acids and bases. There can be no doubt that, in the course of this complete decomposition, iron is set free in the intestine and even in the stomach in its so-called inorganic form; and in the absorption, free hydrochloric is surely an important factor. The HCl, in so far as it is not neutralized by the bile and pancreatic juice, is of considerable importance in the duodenum. Even after neutralization of the HCl from the stomach, the intestinal contents has normally certain acid properties; whether one assumes, as do Macfadyen and Nencki as well as Ogata, that the intestinal contents give a distinct acid reaction, or admits, as does Matthes, a reaction alkaline to litmus and acid to phenolphthalein, corresponding to a solution of sodium bicarbonate containing free CO_2 . In this reaction there is an acid element present in the form of free carbonic acid, which is capable of holding iron salts in solution. We know that this is true because of the iron content of alkaline chalybeate waters and acid salts. The objection that the decomposition of protein is complete only in the lower bowel through the action of erepsin is not sufficient to belittle the importance of HCl for the absorption of iron, since, as Abderhalden¹ has shown, a large part of the albumin is broken up in the stomach into polypeptone, and even in the lower bowel, where the decomposition of protein is surely complete, a deficit in HCl must make itself felt, in that bicarbonate will be more or less changed into mon carbonate.

It seems to the author that the most probable explanation of pernicious anemia, in cases where the suppression of the HCl secretion is demonstrated, consists simply in the disturbance of iron absorption, since in these cases not only does the organism receive insufficient material for blood-formation, but the bone-marrow lacks the physiologic stimulus to the same. The blood-picture in pernicious anemia indicates, therefore, the reaction of the bone-marrow to an insufficient supply of iron for the needs of the intermediate metabolism. The circumstance that plentiful supplies of iron are found in the deposits of hemosiderin in the livers and kidneys of patients dead of pernicious anemia is not inconsistent with this theory, because, apparently, an increased destruction of badly formed red cells is the cause of this phenomenon, and because it is quite conceivable that if the stimulation of the bone-marrow be lacking, owing to the failure of iron absorption, the organism is no longer able to make use of these deposits formed from the destruction of the red cells.

The peculiar reversion of the bone-marrow to the embryonic type of blood-formation, so often emphasized, argues for this theory of pernicious anemia, for the embryo must behave as the patient with achylia, in so far as it does without the stimulus afforded by the absorption of iron. The facts that, as a rule, no benefit results from the administration of iron alone, and that, as the author has often seen, a combination of iron and large amounts of acid often succeeds, are also in accord with the theory. In the former iron is not absorbed in sufficient quantity, owing to the lack of acid. Organic acids, especially lactic acid, which are afterward oxidized in the body are adapted to this purpose, but not HCl (combination of iron with kefir cure). The theory is further supported by the fact that cases of so-called cryptogenetic pernicious anemia always relapse after a time, especially if the acid be not administered continuously, for the achylia is in no way improved. Against the theory it may be argued that marked disturbance of the acid secretion may be found in patients who do not become anemic. But this assertion is usually based on the fact that in many individuals, apparently in perfect health or presenting only gastric derangement, no *free* HCl is found in the stomach-contents. Such disturbances of the secretion, which are by no means always severe, but, in which, indeed, no *free* HCl is found after a test-meal, are often quite wrongly called *achylia*, because sufficient *combined* HCl is present. It should be remembered that the test-breakfast allows of but incomplete conclusions concerning the actual amount of acid secreted during the digestion of an ordinary meal. (See the author's explanations in the discussion of the desmoid reaction, p. 437.) There can be no doubt that a decreased secretion of acid, even to a degree where no free HCl can be demonstrated, may yet suffice to maintain protein digestion and iron absorption. The author has been able to show that not only may no *free* acid be present in cases of pernicious anemia, but that the total acidity is always markedly reduced, and frequently there is no acid at all, the gastric juice being neutral or even alkaline. The severity of the disturbances is shown in these cases by the persistently negative desmoid reaction and the frequent complete absence of pepsin and lab-ferment. That too little attention has

¹ Zeit. f. physiol. Chemie, vol. li, parts 4 and 5.

up to the present been paid to such great and important differences within that large group of gastric disorders characterized by the absence of free HCl (also in stomach pathology) is due, in great part, to the popularity and overestimation of the qualitative tests for free HCl, which, as the author has already pointed out, are inadequate (pp. 437 and 479). The absence of free HCl in the test-breakfast is by no means of the same value in all cases. Besides, it may be that some individuals bear a marked diminution in free HCl better than others. Some have, perhaps, but little need for iron, *i. e.*, there is but slight iron metabolism, so that small traces of iron absorbed from the food suffice to maintain the balance. Variations in the capacity of the intestinal mucosa for absorption also play a part. If once this theory be earnestly tested, it will be demonstrated that the hypochlorhydria of a chronic gastric catarrh can be borne for years, and then finally lead to pernicious anemia through an increase in the disorder or through its long duration. We cannot say how long this latent stage, which ends in outspoken anemia, has lasted; but the fact that years of digestive disturbance often precede anemia leads one to suppose that these cases, too, have passed through a long stage of tolerance. With regard to the final objection that the disorder of the acid secretion may be a *consequence* of anemia, because diminution or absence of free HCl is sometimes, though, by no means constantly, found in other forms of anemia, *e. g.*, chlorosis, it must be pointed out that these secondary disturbances of the acid secretion never attain so high a degree as in pernicious anemia, and that, with the improvement of the anemia, they are improved or cured. This is never the case in pernicious anemia. During periods of improvement the gastric anacidity remains unchanged and is the simplest explanation of the relapse. It is unfortunate that so little work has yet been done to show what happens to the chemistry of the stomach after the parasite has been expelled in bothriocephalus anemia. It is fair to assume that it is improved, because the parasite is of etiologic importance, although the *free* acid, which the author considers irrelevant, may not be reestablished. The author can report a case, however, where the anemia was cured after the expulsion of the worm, but where, despite the evident dependence of the malady on the parasite, with the return of the gastric disorder later, a fatal recrudescence of the anemia occurred, though at autopsy no evidence of a second bothriocephalus was found. This strongly suggests that bothriocephalus also gives rise to anemia by causing achylia or hypochylia. That the hemolytic properties of the bothriocephalus cannot be taken as the cause of the anemia is shown by the fact that evidences of hemolysis are by no means a part of the symptom-complex of pernicious anemia, especially in the early stage. The significance of the demonstration of hemolytic substances in the bothriocephalus must be considered slight until other intestinal parasites have been studied to determine this property, and until it has been shown that ordinary food-stuffs do not contain hemolytic substances. If, finally, as an argument against the author's theory, we advance the fact that the severest degrees of pernicious anemia may be benefited or temporarily cured by the administration of arsenic, though owing to the continuance of the achylia it may not be assumed that the absorption of iron has been improved, it must not be forgotten that it is quite conceivable that the arsenic stimulates the marrow to increased energy, so that it may get along with even *traces* of iron absorbed from the intestine or may mobilize and make use of the hemosiderin deposits which are always present. The iron theory of pernicious anemia is, therefore, so well grounded, and the arguments opposed to it appear to have so little weight, that it demands serious consideration. The author admits that probably other causes must be considered in certain forms, particularly in the puerperal and in those following syphilis, sepsis, and malaria, especially because the changes in gastric chemistry are not completely understood in those affections, for it is quite conceivable that identical forms of disease of the bone-marrow may arise from different causes.

Differential Diagnosis of Pernicious Anemia.—In contradistinction to most other anemias the diagnosis of pernicious is given in the definition, *i. e.*, in the embryonic type of blood-formation, as shown by the blood-picture. We need, therefore, differentiate it only from those anemias which show a similar type of "hematopoiesis," yet are still separately considered, because pernicious anemia is not yet considered a mere symptom-complex, though this, in the author's opinion, is simply a matter of time. Only the distinctive features of the blood-picture will be discussed here. It is, however, clear that the entire *clinical* picture must be considered in the diagnosis. The differentiation of the so-called cryptogenetic form from those due to helminthes, malaria, sepsis, syphilis, and the puerperal state depends on the demonstration of the cause. The following diseases may be confused with the so-called cryptogenetic or true pernicious anemia:

- (1) *Infantile pseudoleukemic anemia* differs from pernicious anemia, first, in the

great numbers of normoblasts which are the rule, while in pernicious anemia they occur in such great numbers only during periods of rapid improvement; second, in the marked leukocytosis; and third, in the much greater increase in the size of the spleen.

(2) *Leukemia* and *pseudoleukemia* may be mistaken for pernicious anemia, especially in the (pseudoleukemic) stages in which the increase in white cells is not striking, for the embryonic type of blood-formation is sometimes observed in these diseases. Most of these cases differ from pernicious by the enlargement of the lymph-nodes, liver, and spleen, besides which the lymphatic forms of these diseases show pathologic lymphoid cells (see p. 793), even if the lymphocytes are not strikingly increased in number.

(3) The anemia due to malignant tumors differs in the high leukocytosis, even when the embryonic type of blood-formation is evident. The author has called especial attention to the fact that certain gastric cancers must be recognized as the cause of the genuine prototype of pernicious anemia, which cannot be differentiated from the forms due to achylia (p. 827).

Anemias Following the Loss of Blood

Acute Loss of Blood.—After an acute hemorrhage the blood becomes rapidly diluted, owing to the absorption of lymph and water. Although the hemoglobin and the number of blood-corpuscles may be normal immediately after a hemorrhage, all the characteristics of oligochromemia soon appear, and persist until a normal condition has again been reached. The decrease in hemoglobin may be very marked, to 20 per cent. (corrected) or less. The red cell count may sink to 400,000. At first the color-index is normal, since, of course, the hemoglobin and the red cells are proportionately decreased. The oligochromemia reaches its maximum within a few hours after a slight hemorrhage, but after severe hemorrhages not until about nine days. Evidence of a regeneration of the blood-corpuscles can be found almost as soon as the plasma begins to be replaced. According to the investigations of Ott and Laache, the number of red blood-corpuscles is normal much sooner than the percentage of hemoglobin. This produces a condition similar to chlorosis, the color-index being less than one. Even from the second day on normoblasts, which not infrequently show mitotic figures, are found (p. 786 et seq.). Immature, non-nucleated erythrocytes showing polychromatophilia appear at the same time. In frank hemorrhage basophilic degeneration is rare. It is observed more frequently in concealed hemorrhage when the iron is reabsorbed. At times the blood may fairly teem with normoblasts (blood crises). Poikilocytosis and anisocytosis are also observed. Megaloblasts may likewise be found if the anemia following hemorrhage be of long duration. Confusion with pernicious anemia is, however, unlikely, because of the post-hemorrhagic leukocytosis, usually polynuclear. Even myelocytes and transition forms may be found. The number of blood-platelets is increased and the coagulation hastened after acute losses of blood. Mikulicz considers that major surgical operations will not prove successful if the hemoglobin sink below 30 per cent. This assumption is rather arbitrary, and the percentage of hemoglobin which would justify an operation might very well be placed a little higher, especially if the anesthesia is to be a prolonged one, as anesthesia exercises some detrimental influence upon the composition of the blood.

Chronic Loss of Blood (Hemorrhoids, Menorrhagia, Chronic Gastric Ulcer, Carcinoma, Ankylostomiasis, etc.).—Generally speaking, the condition of the blood here is very similar to that several days after an acute loss. The number of red blood-corpuscles is, as a rule, not diminished to so great an extent as the hemoglobin, probably on account of the processes of regeneration. The color-index is, therefore, less than 1. The anisocytosis and poikilocytosis, though present, also after acute hemorrhage, as well as the megaloblasts, are more pronounced in chronic bleeding. This is, in all probability due to the continued loss of plasma and the permanent hydremic nature of the blood-plasma. Another difference is that the leukocytes are not increased in the severe cases of anemia following chronic hemorrhages, and so the picture approaches more and more that of pernicious anemia, without, however (especially in regard to the color-index and the volume quotient) coinciding with it exactly. The number of polynuclear leukocytes is an approximate measure of the regenerative activity of the bone-marrow in the anemias following hemorrhage. The presence of nucleated blood-corpuscles is another index.

ERYTHREMIA OR POLYCYTHEMIA (POLYCYTHEMIA VERA OR RUBRA, POLYGLOBULIA)

Numerous descriptions have recently appeared, the first coming from French writers,¹ of a peculiar affection of middle-aged adults, which consists essentially of a more or less marked increase of the erythrocytes and of the hemoglobin, associated with splenic enlargement, and, further, is characterized clinically by a marked redness or cyanosis of the face, headache, attacks of vomiting, slight albuminuria with casts, and the presence of blood in the sputum, vomitus, and feces. The autopsy findings indicate that, in addition to the increased number of erythrocytes, there is also a true plethora, since all parts of the body seem to contain an excessive quantity of blood. The heart is normal or somewhat enlarged. In several cases the blood-pressure was found to be increased. The disease appears in middle life and lasts for many years. As yet there is no accurate information as to any change in the bone-marrow. Careful examinations of the blood in these cases show that the number of erythrocytes may be increased to 12,000,000 per c.mm., and the hemoglobin to 200 per cent. (corrected). Such high values are, however, rare. Usually the hemoglobin is about 120 per cent. (corrected) and the color-index is less than 1. The number of leukocytes varies. Türk always found leukocytosis (up to 36,000) in his cases. It may be absent (in about one-half the cases). Myelocytes may be present; the eosinophiles and mast-cells may be increased; polychromatophilia, anisochromemia, normoblasts, and myeloblasts may be noted. The specific gravity of the blood is increased. The same is true of the viscosity of the total blood and of the plasma alone (Kottmann). It is still doubtful whether all cases answering to this description are one and the same affection. Türk believes that, in some of the cases at least, there is a primary hyperplasia of the erythroblastic bone-marrow, with increased function. In favor of this conception is the frequently occurring leukocytosis and the finding of myelocytes. Türk has suggested the name of erythremia or erythrocythemia for this disease, and contrasts it with myeloid leukemia, as the red cell analogue of the latter. The author believes, however, that all cases described in the literature are not to be considered one and the same malady. The blood-picture in chronic stasis may simulate polycythemia because of the retention of the corpuscles in the capillaries on account of the slow current; or polycythemia may result from it, since certain organs, in consequence of this "sifting" of the corpuscles, contain too little hemoglobin, and, therefore, more active blood-formation results, due to functional adaptation of the bone-marrow. The abnormally high blood-counts are in favor of this possibility. It cannot be said that there is no primary erythremia like that described by Türk. However, such a diagnosis should be guarded, and one should not fail to recognize the condition due to stasis. The following case of the author's is interesting from the standpoint of the pathology of erythremia and of iron therapy. A severe chlorosis was so benefited by the administration of iron that the hemoglobin rose to normal and the red cell count to 8,000,000.

[A case of erythremia recently reported by Kinnicut showed the following condition of the blood in addition to the findings noted above: Viscosity 2.7 times normal, specific gravity 1065, total volume of blood per 100 gms. body weight nearly twice normal, red cells 75 per cent. of the volume of the blood. Coagulation time decreased. Stern² reports finding a strikingly red marrow in the long bones. It almost, if not quite, replaces the normal yellow marrow. In it there is often a distinct increase in the nucleated erythrocytes. Weber,³ in an analysis of 25 cases, found that much of the bone-marrow is converted from normal (fatty) to red (active blood-forming). In one case a large proportion of "non-granulated mononuclear myelocytes" or "myeloblasts" were reported. There is thus an increase in erythro- and leukoblastic tissue, the latter often predominating. The splenomegaly seems to be due in part to engorgement, in part, to hyperplasia.—ED.]

LEUKEMIA

The chief characteristic of leukemia is a considerable and permanent pathologic increase of the mononuclear leukocytes in patients who do not exhibit, aside from

the changes in the blood-forming organs (the bone-marrow, spleen, and lymph-nodes) any other lesions which may be considered primary.

Formerly leukocytosis was separated from leukemia, in a very arbitrary way, according to the degree of increase of the white blood-corpuscles. If the proportion of white to red cells reached from 1 : 50 to 1 : 20, the affection was called leukemia. This method of differentiation was shown to be useless in the early studies of leukemia and in cases of severe leukocytosis associated with marked anemia. When Ehrlich emphasized the frequency of the eosinophilic leukocytes in myeloid leukemic blood, it was at first believed that he had found a reliable point of differentiation between leukemia and leukocytosis, but it did not prove to be a correct one. Since the morphology of the leukocytes has been more accurately studied, it has been found that the difference between leukemia and leukocytosis is neither one of gradation nor one depending upon the tinctorial properties of the leukocytic granules, but that the true difference lies in the fact that in leukemia there is a very great increase in the mononuclear cells which dominate the blood-picture to a marked degree, and may even exceed the numbers of the polynuclear type. However, this does not sharply define leukemia, because there are other diseases with striking increases in the mononuclear elements, and because the blood-picture in leukemia may present wide variations, so that temporarily it hardly differs from that of a leukocytosis or some other blood disease or, indeed, from normal blood. A definite conception of the disease can, in reality, therefore, be formed only from the whole clinical picture and from an understanding of its pathology.

Since *lymphatic* is to be sharply differentiated from *myeloid leukemia*, the pathologic processes which determine the different types must be described separately. But it is necessary to consider the historic development of the classification in order to understand them.

Leukemias were formerly classified, according to the associated changes in the organs, as *splenic*, *myelogenous*, and *lymphatic*, to which transition or mixed forms were added. This classification is no longer tenable from a modern hematologic standpoint. The blood and also the *histologic* changes in the organs, which show, in one case, an increase in the *myeloid*, in another an increase in the *lymphatic*, tissue must nowadays be considered as deciding the classification.

How inaccurate a classification based on macroscopic changes must be, is shown by the fact that such findings cannot be sharply differentiated from one another. Thus, in lymphatic leukemia, for example, even if the hyperplastic lymph-nodes are, as a rule, most striking, yet quite regularly the lymphatic tissue disseminated throughout the body, including that in the bone-marrow and spleen, is equally hyperplastic, and the latter organ will be much enlarged. The assumption that a purely splenic leukemia, i. e., one due essentially to disease of the spleen, may occur is equally untenable. Besides, according to recent studies, the spleen has but little to do with blood-formation in adults, and it may be shown that even in those leukemias which seem to deserve the name splenic, because of the great size of the spleen, not only are constant changes found in the bone-marrow, but the spleen itself undergoes *myeloid* degeneration, and it is the *myeloid* elements of the blood which are increased in numbers. Finally, with the establishment of the fact that so-called splenic leukemia is really a myeloid form, the distinction between splenic and myelogenous leukemia loses its old significance. The clinical conception of mixed forms (e. g., the splenolymphatic, lymphatic myelogenous, etc.), is, therefore, of no value, since in this gross sense practically all forms are mixed.

Ehrlich and Lazarus have recommended subdividing leukemia into two types, based upon the blood-examination: lymphoid leukemia or lymphemia and myeloid leukemia or myelemia. The associated changes in the organs may be described in connection with these terms; for instance, a lymphemia with splenic tumor, or a myelemia with a splenic tumor and swelling of the lymph-nodes. Besides the older terms, lymphatic and myelogenous are not analogous to the present ones, lymphoid and myeloid, because with the older names, as the expression myelogenous shows, the old idea of the origin of the increased leukocytes persisted, whereas the terms lymphoid and myeloid refer to the character of the hyperplastic tissue and not to diseased organs. This tissue is known to be disseminated throughout the body or (the myeloid) at least to develop everywhere. The new names lymphoid and myeloid accordingly imply the existence of a systemic disease characterized by hyperplasia of the lymphoid tissue, on the one hand, and of the myeloid tissue, on the other. This involves every part of the body where the anatomic character of the tissue permits. According to Nägeli, the generalization of this hyperplasia does not depend upon metastases, as in the case of malignant tumors, but upon the almost ubiquitous presence of preformed lymphoid tissue, and upon the fact that it, like myeloid tissue,

can be developed everywhere in the adventitia of the vessels, metaplastically. (See Nägeli, *Blutkrankheiten und Blutdiagnostik*, 1907, pp. 179 and 133.)

Leukemia may, therefore, be defined as a systemic disease, characterized by hyperplasia of preformed lymphoid or myeloid tissue, or of their forerunners, in which, in addition to hyperplasia in the organs, the blood is more or less overrun with hyperplastic cells.

For a long time there has been a tendency to abandon the sharp distinction formerly drawn between so-called lymphoid and myeloid leukemia; because in myeloid leukemia cells resembling lymphocytes do appear in the blood. The phenomenon was originally explained by assuming that the bone-marrow might produce lymphocytes even under normal conditions, so that in a leukemia arising from this organ the lymphocytes would naturally be increased. These were the cases which were formerly termed mixed-cell leukemias, because it was thought that they presented to a certain degree a mixture of the two types of leukemia. One still encounters this expression in the literature.

It is difficult to conceive of the blending of two diseases so fundamentally different, both clinically and morphologically, as lymphoid and myeloid leukemia, because the lymphoid and myeloid tissue and their corresponding cells in the blood, both in their numbers and their proportions, behave like antagonists. Nägeli has, however, the author believes, solved the difficulty by showing that the cells resembling lymphocytes, which are found in large numbers in an otherwise characteristic myeloid leukemia, and which might be called lymphoid cells, are not true lymphocytes, but immature, undifferentiated marrow-cells, which he calls *myeloblasts*. The characteristics which distinguish these cells from lymphocytes have been given above (p. 793, Pl. 5, Fig. 1, *f*, and Fig. 3, No. 21, and Pl. 6, Fig. 2, No. 14).

CHRONIC LYMPHOID LEUKEMIA (CHRONIC LYMPHATIC LEUKEMIA)

(See Pl. 8, Fig. 4)

The essential characteristic of the blood-picture in this disease is the absolute and relative increase in the lymphocytes up to 90 per cent., or, indeed, to 99 per cent., of the total leukocyte count. The small lymphocytes usually predominate. The absolute number may be several hundred thousand, rarely over one million. There is rarely an absolute increase in the other leukocytes. Myelocytes are seldom present and then sparsely. Eosinophiles and mast-cells are few. The hemoglobin, as well as the number of red cells, may remain normal for a long time. Later there is an oligochromemia and a decrease in the number of the red cells. Then the blood-picture resembles that of pernicious anemia (megaloblasts, normoblasts, anisocytosis, megalocytes, polychromatophilia, and basophilic stippling of the red cells). The blood of chronic lymphoid leukemia has no striking macroscopic characteristics except the oligochromemia; never the yellow color sometimes observed in myeloid leukemia. The dilution made for hemoglobin estimation is often turbid, because the lymphocytes are not dissolved.

Nägeli, in particular, has shown that the lymphocytes present the following variations from normal cells. These are of especial importance in the diagnosis if the increase in the leukocytes be not marked.

1. The protoplasm may be even more scanty than in normal cells, and recognizable only as a narrow margin around the almost naked nucleus.

2. The nucleus often contains less chromatin, and, therefore, when stained, appears lighter than normal. (See Pl. 5, Fig. 3.)

3. The size of the lymphocytes varies more than normally. Besides the small cells, large lymphocytes with pale nuclei are always present. (See p. 793 and Pl. 4, Fig. 3.) The number of these cells usually increases during the acute exacerbations of the disease, thus bridging the gap between it and acute lymphoid leukemia. Some of the large lymphocytes show lobulation and cleavage of the nuclei, described by Rieder. (See p. 793 and Pl. 5, Fig. 3, Nos. 22 and 23.)

4. Sometimes these large lymphocytes predominate, as in the case of acute lymphoid leukemia.

5. The azure granulations present in one-third of all normal lymphocytes are usually absent in lymphatic leukemia (Nägeli). However, the author has also found them in this disease.

The protozoan cellular parasites found by Löwit and Mannaberg, but not confirmed by other writers, cannot be discussed here.

In regard to the other clinical findings, attention should be called to the usually extensive swelling of the lymph-nodes, particularly those of the neck, in which it usually begins. These may vary from the size of a bean to that of an apple. They are usually not adherent to the skin, and rarely break down or discharge, even if they

PLATE 8.

Normal blood. In the field of vision a lymphocyte, a polynuclear cell, and an eosinophile one. The nuclei of all the white cells dark blue, the eosinophile granulations a brilliant red (Rieder).

Inflammatory leukocytosis. Marked increase of polynuclear leukocytes. Representation of their neutrophile granules (Rieder).

Heart-disease cells from fresh sputum-preparation (Jakob).

Lymphatic leukemia. Almost all the white blood-corpuscles uninuclear (lymphocytes), most of them very small (Rieder).

Leucomyelogenic leukemia. Most of the white cells are uninuclear; many are strikingly large, with large, plump nucleus. Several eosinophile cells. One nucleus contains red blood-corpuscles (Rieder).

are very soft to the touch. The spleen is almost always enlarged, but usually to a moderate degree, rarely attaining the enormous size of the spleen of myeloid leukemia. The bones may be sensitive to percussion. Affections of the skin are very frequent and quite characteristic of chronic lymphatic leukemia. Pruritus, urticarial eruptions, and lymphoma-like growths of the skin, which may develop into large tumors, occur, particularly in the face (lymphoderm perniciosa). Lymphomatous tumors of the tonsils and of the lingual follicles, as well as of the salivary and lacrimal glands, and infiltration of mucous membranes, may develop, and by ulceration may give rise to hemorrhage. The liver also may be more or less increased in size, sometimes resembling a tumor. The Bence-Jones protein may be demonstrated in the urine. The eye-grounds often show hemorrhages, fatty degeneration, and infiltration of the retina. Even hemorrhages into the skin and mucous membranes may occur.

ACUTE LYMPHOID LEUKEMIA (ACUTE LYMPHATIC LEUKEMIA)

(See Pl. 8, Fig. 4)

The blood-findings in acute lymphoid leukemia are, on the whole, similar to those of the chronic form, but the oligochromemia is usually much more pronounced. The same turbidity is often noted in the dilutions made for hemoglobin estimations. There are the same predominance of lymphocytes and the same relative suppression of the other white elements. One peculiarity is that the increase in the lymphocytes in some cases (failure of the lymphoid tissue to react) may remain relatively slight (*e. g.*, 20,000). Sometimes, to be sure, excessive numbers (up to 200,000) are present. The counts may be subnormal for short periods at the beginning of the disease and just before death. This last finding shows the transition to acute pseudoleukemia which, under the form of a hemorrhagic diathesis and severe anemia may rapidly prove fatal. The pathologic lymphocytes, especially the larger forms (p. 793), which stain with difficulty, usually predominate. They are of importance in the diagnosis of cases where the number of lymphocytes is not at all or but little increased. However, large forms may be persistently absent from the blood in the acute type. The lymphocytes usually lack azure granulations (Nägeli), in contradistinction to the normal lymphocytes, though the author has found exceptions to this rule, precisely as in chronic lymphoid leukemia.

In its general clinical course acute lymphatic leukemia bears about the same relation to the chronic form as an acute infectious disease of high virulence bears to a milder, chronic infection. It is hardly possible to draw a sharp line between acute and chronic leukemia merely from the duration. The difference between the very acute (lasting a few days) and the very chronic (lasting several years) is quite plain. A sudden onset with pronounced symptoms is particularly characteristic of the acute form. The acute form not infrequently occurs in young people, even in children, whereas to the best of the author's knowledge the chronic form has never been observed in early life. The most acute cases (frequently not diagnosed) may rapidly prove fatal, simulating a severe purpura (so-called morbus maculosus Werlhofii) (p. 841). Other cases assume the characteristics of scorbutus or of a gangrenous (frequently hemorrhagic) septic angina, and are recognized only after examination of the blood. The hemorrhagic diathesis plays an important rôle in the clinical picture of acute lymphoid leukemia. Cutaneous hemorrhages are more common than in the chronic forms, but the skin affections are comparatively rare. The lymph-nodes show less tendency to swelling and may not be enlarged at all—a symptom which is extremely misleading. The spleen is, indeed, enlarged, but less markedly than in the chronic form. The same is true of the liver.

Acute lymphoid leukemia may occur in combination with chloroma (so-called *chloroleukemia*, Nægeli). Its place in the classification is shown in the table on p. 838.

CHRONIC MYELOID LEUKEMIA (MYELEMIA)

(See Pl. 8, Fig. 5, Pl. 4, Fig. 2, and Pl. 5, Fig. 1)

The chief peculiarity of the blood-picture in myeloid leukemia is the presence of numerous leukocytic elements originating in the bone-marrow. The number of such cells is often enormous (up to 300,000 or 400,000 or over). The presence of great numbers of myelocytes is particularly characteristic, although the polynuclear or polymorphonuclear leukocytes usually predominate both absolutely and relatively. The polynuclear neutrophiles may be 80 per cent. of the total count. Even the polymorphonuclear eosinophiles and the mast-cells are absolutely and sometimes relatively increased in number. The neutrophile myelocytes may con-

stitute 40 per cent. of the total count, and the total myelocyte count (neutrophile, eosinophile, and basophile) may exceed that of the polymorphonuclears. The eosinophile myelocytes are numerous, and basophile or mast-cell myelocytes are present in varying numbers. The blood also contains more or fewer myeloblasts, which, according to Nägeli, make up 1 per cent. to 3 per cent. of the total leukocyte count. Large mononuclear cells are scanty, but, according to the author's observations, the transition forms are often numerous. The lymphocytes are relatively diminished, but their absolute number is usually somewhat increased. They are easily confused with myeloblasts, a fact which has led to the erroneous conception of a mixed cell lymphatic myelogenous leukemia in cases where the latter cells are numerous (see below). According to Nägeli, they are best differentiated by the number of nucleoli, lymphocytes never having more than two, while myeloblasts possess three or more (Giemsa's, Leishman, or pyronin methyl-green stains, Pl. 5, Fig. 3, No. 24). The presence of abnormally small, so-called dwarf forms of all varieties of leukocytes, especially the polynuclear neutrophiles and the neutrophile myelocytes, is noteworthy (Pl. 5, Fig. 1). The number and appearance as well as the size of the granules vary greatly. Basophile granulations are found in the eosinophile and neutrophile cells interspersed among the granulations peculiar to the latter. They are regarded as immature forms of such normal granules (Pl. 5, Fig. 3, No. 15). Cells in which the granules are barely visible and appear to be just developing are not uncommon. One should, however, exercise caution in judging of granulations in Jenner, Giemsa, or Leishman preparations. These stains are not always satisfactory and may lead to error, because not all of the granulations are brought out clearly. To the inexperienced observer, the numerous abnormal forms are particularly confusing. They are not always to be classified with absolute certainty, even by an expert. The constant and distinguishing characteristic is, however, the enormous number of mononuclear elements of the bone-marrow, with characteristic granulations, which are, for the most part, neutrophilic, but also in almost every case eosinophilic and basophilic. In making a diagnosis it is strongly advisable not to be content with the relative (percentage) counts of the individual varieties of cells, but to calculate the absolute number. Thus, conclusions as to what cells are really increased in number may be reached, whereas mere differential counts leave one in doubt on this point. Temporary changes in the blood-picture may be represented by curves of the individual cell types.

There is usually moderate oligochromemia and a moderate diminution in the number of red cells. The color-index is about 1. Anisocytosis and moderate poikilocytosis are usually present, while in severe cases megalocytes may be found. As a rule, polychromatophilia, basophilic degeneration, and normoblasts, megaloblasts, and intermediate forms of nucleated red cells are found. The blood-plates are usually increased in numbers.

In consequence of its large content of myeloid cells the blood gives a distinct oxydase reaction (p. 856 et seq.) in the presence of guaiac without turpentine. In severe cases the blood may appear yellowish or ochre colored. The blood and the plasma itself are very viscid (Kottmann), so that good smears are very difficult to make. The dilutions made in estimating the hemoglobin are often turbid from the presence of leukocytes. It is interesting to note that Charcot's crystals have been seen repeatedly in fresh preparations, though, little attention has been paid to them. They seem to depend on the increase of eosinophiles and are regarded as derivatives of the latter. (See p. 707 et seq.)

The blood-picture described above may present many variations even while the patient is under observation. The number of the cells with eosinophile and basophile granulations is particularly variable. According to Lazarus, mast-cells and basophile myelocytes may be 47 per cent. of the total leukocytes. In rare cases the neutrophile cells are very few (Schleip). On account of the unreliability of Jenner's, Leishman's, and Giemsa's stains in this respect the author would strongly advise caution in making such an assumption without studying triacid preparations. Nägeli occasionally found enormous numbers of myeloblasts (in one case, 54 per cent. of 268,000). He calls such cases *myeloblasthemia*; or if such increase be permanent, *myeloblastic leukemia*. Such cases may be mistaken for lymphoid leukemia. In regard to the avoidance of such mistakes through the distinction of lymphocytes and myeloblasts see pp. 793 and 836. In cases where the myeloblasts are so markedly increased, transition forms between myeloblasts and myelocytes are usually found. These cells resemble myelocytes, but contain few granules. Nägeli, with some reason, considers the alleged transition between myeloid and lymphoid leukemia to be in reality a transition between ordinary myeloid leukemia and myeloblastic leukemia. All kinds of anomalies are observed during the administration of arsenic or treat-

ment with x-rays. It is further noteworthy that in intercurrent infections the total leukocytes may be markedly decreased, so that the blood-picture may be transformed into a simple polynuclear leukocytosis or may become almost normal. Under such circumstances the myelocytes may nearly all disappear. Quincke¹ has observed a similar change after tuberculin injections, and it may occur without evident cause.

Among the other clinical signs of myeloid leukemia should be mentioned, first of all, a frequently enormous increase in the size of the hardened spleen. (See Fig. 170, p. 379.) Over it, one not uncommonly hears perisplenic friction sounds, probably often due to infarction. The liver is usually greatly enlarged. The lymph-nodes may or may not be enlarged. They are seldom so large as in lymphoid leukemia. Chronic nephritis and ascites, the fluid containing myelocytes, are not uncommon. There may be a febrile rise in temperature. The eye-grounds often exhibit hemorrhages, areas of degeneration on the retina, and a peculiar thickening of the vessel-walls, due to infiltration of the adventitia with leukocytes. In the urine, uric acid and alloxuric bodies are often increased, and uric-acid crystals and amorphous urates are found in the sediment.

Löwit's observations of protozoan cellular parasites in the leukocytes have not been confirmed.

The *diagnosis* of myeloid leukemia is usually easy, the more so as the large splenic tumor suggests it and calls for a complete examination of the blood. Despite this, however, there are cases which are difficult to distinguish from marked leukocytosis with numerous myelocytes. According to Engel, these may be 10 per cent. (in diphtheria); according to Nägeli, 25 per cent. (in pernicious anemia complicated by sepsis). In such cases the absence of eosinophiles (except in scarlet fever) and mast-cells usually excludes leukemia. Unless the other clinical symptoms are considered, the large numbers of myelocytes and the high leukocytosis sometimes seen in multiple myeloma (p. 841) and in granuloma (p. 839 et seq.) cannot always be differentiated from myeloid leukemia. The difficulty here probably depends on the fact that in these cases the condition of the bone-marrow is very closely related to, if not identical with, that of leukemia. This applies with equal force to the sometimes striking increase in myelocytes in infantile pseudoleukemic anemia. The facts that the disease runs a more favorable course and that true myeloid leukemia is not apt to occur in early infancy are all that serve to establish a diagnosis. For so-called leukanemia see p. 839.

ACUTE MYELOID LEUKEMIA (ACUTE MYELOBLASTIC LEUKEMIA, NÄGELI)

Acute myeloid leukemia has been recognized but a few years because formerly all acute leukemias were considered lymphatic. The monocellular elements found in the blood of this form resemble lymphocytes. They are, so to speak, lymphoid cells. Careful investigation shows, however, that these cells are the myeloblasts described by Nägeli, i. e., they look like lymphocytes, but belong to the myelocyte order of still undifferentiated marrow-cells. The chief evidence in favor of this view is the presence of transition forms between these structures and the myelocytes. In cases of this disease an enormous number of myeloblasts may be found (up to 75 per cent. of the total leukocytes). The malady may prove fatal in a few weeks, grave symptoms of a hemorrhagic nature, ulcerative stomatitis, and severe anemia supervening. There may be no swelling of the lymph-nodes, and in contrast to the chronic form, even the spleen may be but slightly enlarged.

THE LYMPHOMATOSES AND THE LYMPHOID PSEUDOLEUKEMIAS

Under the name lymphoid or lymphatic pseudoleukemia have been grouped a number of diseases which, although without the typical blood-picture, do resemble leukemia so far as the condition of the lymph-nodes and spleen are concerned and which are, therefore, conceived to be systemic diseases of the lymphoid tissue.

They are probably, however, closely related to leukemia in character, as is indicated by the existence of transition forms of true leukemia. Since the occurrence of transition types between the aleukemic and the leukemic forms, as well as the relationship of the two diseases is generally accepted, lymphoid leukemia and lymphoid pseudoleukemia have been grouped together under the general term lymphomatosis or lymphocytomatosis. In addition the sublymphemic forms are distinguished from the aleukemic and the leukemic, as well as the intermediate types. The interrelations of the individual types are represented in the table below. To

¹ Deut Arch. f. klin. Med., 1902, vol. lxxvi.

complete the presentation of the terminology it may be stated that Pappenheim, regarding multiple myeloma of the bones (Kahler's disease, see p. 841) as the myeloid analogue of lymphoid pseudoleukemia, calls it *myeloid pseudoleukemia*.

Certain types designated *lymphosarcoma* (Kundrat) have been distinguished from the aleukemic lymphomatosis, though they present the same histologic picture. They differ from true sarcoma in this respect, but resemble it in that they are, at least in the beginning, localized and later become general by metastasis after the manner of malignant tumors. The author finds this distinction very difficult to apply. It cannot be considered a criterion for distinguishing infiltrating tumors, and is more properly applied to pseudoleukemic lymphomatosis, as is brought out in the table below, because many cases of the latter which later impress one as systemic diseases may begin as local manifestations. This is true of many lymphomata leading to pronounced leukemia.

Moreover, there has arisen a considerable clinical difficulty since the demonstration of a greater variability than was formerly supposed to exist in the diseases which present the macroscopic picture of lymphoid pseudoleukemia and which are accompanied by generalized enlargement of the lymph-nodes and spleen. Beside, the affections just described, appropriately named pseudoleukemic lymphomatosis, there are others which, despite a superficial resemblance to the general clinical picture of lymphoma, exhibit a very different histology. Instead of an exclusive proliferation of the lymphocytes, we find a polymorphous cell picture consisting of large endothelioid cells, fibroblasts, epithelioid cells, and giant-cells mixed with lymphocytes, thus resembling inflammatory granulation tissue, so that, following the example of Kundrat and Benda, the enlarged nodes have been called *granulomata*. Even these granulomata are often just as generalized systemic diseases (*granulomatosis*) as are the true lymphomatoses. Hence the clinical differentiation is naturally very difficult. For some of these (malignant granulomata) no cause has been demonstrated, whereas others, because of their content of tubercles and giant-cells, are known to be tuberculous and still others luetic. These granulomata must, therefore, be distinguished from the true lymphomatoses.

The clinical differentiation of true pseudoleukemic lymphomatosis from granulomatosis is sometimes extremely difficult, because neither influences the blood-picture to any marked degree. The blood in the former, however, usually shows certain distinctive peculiarities which are discussed below.

A CLASSIFICATION OF THE TRUE LYMPHOMATOSES (Excluding granulomatoses)

	Generalized.				Localized but forming metastases.
	Chronic.		Acute.		
	Benign. ¹	Malignant.	Benign.	Malignant.	
1. Alymphehic	True lymphoid pseudoleukemia.	Alymphehic, lymphosarco- matosis.	Acute lymphoid pseudoleuke- mia.	Alymphehic chloroma.	Lympho- sarcoma, strictly speaking (Kundrat).
2. Sublymphhehic		Sublymphhehic lymphosarco- matosis.		Sublymph- hehic chlor- oma.	
3. Lymphhehic.	Chronic lymphoid leukemia.	Lymphhehic lymphosarco- matosis.	Acute lymphoid leukemia.	Lymphhehic chloroma (Nägeli).	

True Lymphoid Pseudoleukemia.—Under this title are usually included the aleukemic and sublymphhehic forms of the lymphomatoses, excluding chloromata and the localized lymphosarcomata (Kundrat). The sublymphhehic forms are most frequently and most surely to be diagnosed as true lymphomatoses. The characteristic to which Pincus has called attention, and which has recently been considered pathognomonic of these cases, is a so-called relative lymphocytosis. Thus the lymphocytes may make up 70 to 90 per cent. of a normal or slightly increased total count of 5000 to 10,000. This finding indicates the relation of this type to the lymphatic form, *i. e.*, lymphoid leukemia. For, as a matter of fact, the lymphocytes in

¹ The terms benign and malignant are here used in the pathologic-anatomic sense. Malignant refers to aggressive growths which proliferate into and destroy neighboring tissues; benign, to the opposite. The anatomically benign forms may, of course, be malignant from a clinical or prognostic standpoint.

these so-called relative lymphocytoses are also *absolutely* increased, and it would, therefore, seem more suitable to consider not a relative, but an absolute, increase of the lymphocytes as a distinguishing characteristic, and to term it the "sublymphemic constitution," since this would give a clearer idea of the nature of the change. The indefinite boundary between this malady and lymphoid leukemia depends on the nature of the case. A sharp line between pseudoleukemia and leukemia cannot be drawn because, as we have seen, in certain stages of the latter, particularly in *acute* lymphoid leukemia, the lymphocyte increase may be lacking, and, on the other hand, pseudoleukemia may temporarily assume a true leukemic blood-picture. For the diagnosis of this sublymphemic condition it is also essential that there be many lymphocytes of the atypical form described on p. 834 (Nägeli). These cells are not, however, pathognomonic, because they may occur also in other lymphocytoses *e. g.*, in typhoid fever. The blood in these cases shows a certain degree of anemia with the same characteristics as in lymphoid leukemia (p. 834).

The remaining clinical picture of true lymphoid pseudoleukemia is characterized by: (1) Enlargement of the lymph-nodes and spleen; (2) absence of fever and of the diazo-reaction; (3) the frequent appearance of signs of a hemorrhagic diathesis in the later stages; (4) an infiltration with lymphocytes of the skin of the eyelids and mammae and of the mucous membranes of the mouth, throat, and pharynx.

There are also *acute* forms of lymphoid pseudoleukemia (see table p. 838), which, as morbus maculosus Werlhofii rapidly prove fatal. These are rarely connected with the swelling of the lymph-nodes and need not give rise to any sublymphemic peculiarity of the blood. In such cases the diagnosis is often made only after histologic examination of the lymph-nodes. (See p. 841.)

Kundrat's Lymphosarcoma.—According to Nägeli, the blood-picture of localized, so-called *Kundrat's, lymphosarcoma* differs from that of true pseudoleukemia by the frequent occurrence of a neutrophile leukocytosis and a relative diminution of the lymphocytes. The chief point in the differential diagnosis is, however, the absence of absolute generalization and the relatively slight involvement of the spleen and liver. However, this is not an unrestricted criterion, at least in the early stages, because even true lymphatic leukemia may occur in the form of a tumor limited at first to the cervical or mediastinal nodes. Precisely for this reason, since even the blood-findings are not always decisive, the author considers the clinical diagnosis of Kundrat's lymphosarcoma very difficult.

Granulomatosis.—According to Nägeli, some cases of granulomatosis give rise to a marked neutrophile leukocytosis (up to 50,000), sometimes with eosinophilia and frequently with numbers of myelocytes. The lymphocytes are absolutely and relatively diminished because of the involvement of the lymph-nodes. Sometimes there are periods in which the mast-cells are increased. There may or may not be anemia. Nägeli found polychromatophilia and basophilic degeneration of the red cells without oligochromemia in one case due to tuberculosis.

The clinical picture is, however, to be differentiated from that of true lymphoid pseudoleukemia by the absence of a hemorrhagic diathesis and of infiltration of the skin and mucous membranes. The spleen may be swollen. Fever and the diazo-reaction are frequently observed. There is a characteristic alternation of febrile and afebrile periods (chronic relapsing fever, Ebstein). It is worth noting that in tuberculous granulomatosis the tuberculin test is often negative. The injection of tuberculin into the lymph-nodes should be tried, of course, only with extreme caution. The results of antisyphilitic treatment are naturally of great importance for the diagnosis of specific granuloma.

THE SO-CALLED LEUKANEMIA

Under this name Leube and Arneth,¹ and subsequently Luce,² have described blood-affections in which the phenomena of myelogenous leukemia and pernicious anemia occurred simultaneously (myelocytes, megaloblasts, red metaplasia of the bone-marrow). There is no doubt that some of these cases should be regarded as a species of myeloid leukemia. Later observations have shown, however, that these cases hardly form a uniform and independent malady, but that some may be regarded as true pernicious anemia, in which Schindler has proved the presence of myelocytes, and some as myeloid pseudoleukemia. (See Kahler's disease, p. 841.) For a criticism of the theory of "leukanemia" see Morawitz, Deut. Arch. f. klin. Med., 1907, vol. lxxxviii, parts 4 and 5.

THE BLOOD IN PARASITIC DISEASES

In regard to the eosinophilia occurring in all these diseases see p. 808.

Ankylostoma Duodenale.—The anemia resulting from an infection with this parasite may be of high grade. The red cells may fall to 1,500,000, the hemoglobin to 18 per cent. In contrast to pernicious anemia the color-index is usually less than 1. The author can find no data relative to the presence or absence of megaloblasts. With the increase of the anemia the eosinophiles disappear.

Bothriocephalus Latus.—In those cases which give rise to anemia the picture typical of the pernicious form is presented (with megaloblasts, megalocytes, increase in the color-index, polychromatophilia, and basophile stippling of the red cells, poikilocytosis, and leukopenia). Also aplastic forms without megaloblasts and with a yellow bone-marrow have been described. As the symptoms of anemia become pronounced, the eosinophilia previously present decreases and finally disappears. After the expulsion of the parasite there is usually an immediate improvement or, indeed, a permanent cure. Exceptions to this do, however, occur. The author has personally observed a relapse in a case which showed at autopsy that the parasite had been quite expelled and that the persistent achylia was the deciding etiologic factor. (See p. 827 et seq. on the character and cause of pernicious anemia.)

Tenia.—In the rare cases in which tenia causes a severe anemia the findings correspond to those of pernicious anemia. In such cases also the anemia is not always promptly nor completely cured after the expulsion of the parasite.

Echinococcus.—In this disease there is a practically constant relative eosinophilia, sometimes as high as 57 per cent. of the total leukocyte count. This is a great aid in the diagnosis of doubtful cases. Sometimes there is a slight increase in the total leukocyte count. According to Rossello (Soc. de biol. sem. méd., 1907, No. 47), the eosinophilia persists as long as the parasite lives, but disappears with its spontaneous or operative destruction. If other causes can be excluded, the persistence of eosinophilia after operation indicates the existence of a second echinococcus.

Trichocephalus.—*Trichocephalus dispar* also may give rise to severe anemia (see p. 524), but not of the pernicious type. More often the leukocytes are increased in number and the color-index is less than 1.

Filaria Sanguinis.—Besides the embryos, eosinophilia, polynuclear leukocytosis, lymphocytosis, and an increase in the large mononuclears may be demonstrated in the blood of patients with this disease.

Distomum hæmatobium (*Bilharzia hæmatobium*) not uncommonly causes severe anemia in addition to the characteristic symptoms referable to the urinary tract. There is a leukocytosis, eosinophiles are present, and the color-index is low.

Trichinosis gives rise to a marked eosinophilia and often to a pronounced leukocytosis (up to 30,000). The former varies directly with the severity of the disease. Sometimes neutrophile as well as eosinophile leukocytosis is found. An increase in lymphocytes and platelets is noted during convalescence (see p. 809, note 1, for references). In regard to the demonstration of trichina embryos in the blood, see p. 823 et seq.

THE BLOOD IN CERTAIN OTHER DISEASES

BANTI'S DISEASE AND SPLENOMEGALY

Banti's disease and splenomegaly must be discussed together because there is no distinct boundary between them, and because in the former the splenic tumor is, at first, frequently the only symptom. The symptom-complex described by Banti includes a marked enlargement of the spleen of great chronicity, usually combined with anemia and sometimes an irregular fever, which, it is claimed, is later combined with cirrhosis of the liver, also of long duration. After a transition period of icterus and digestive derangement, ascites, severe anemia, and sometimes gastric and intestinal hemorrhages supervene and terminate fatally.

We cannot discuss here the quite obscure pathology of this malady. Banti himself assumes that it consists in a primary toxic disease of the spleen which gives rise secondarily to cirrhosis of the liver, with ascites and to severe anemia. Other pathologists consider it merely a form of cirrhosis of the liver. It is still uncertain whether all cases which present Banti's symptom-complex should be classed together. Congenital syphilis, for example, may cause a similar group of symptoms (Chiari). It is naturally difficult to say anything definite about the blood-findings so long as the question whether the disease is a pathologic entity or merely a symptom-complex remains undecided. In one case Nägeli found a diminution of hemoglobin to

70 per cent. and a decrease in the leukocytes to 3000, of which 68 per cent. were neutrophiles, 17 per cent. lymphocytes, and 4½ per cent. eosinophiles. He found a very similar count in an eighteen-year-old girl with syphilitic cirrhosis of the liver. Nägeli also observed polychromatophilia and basophile stippling, and, after a splenectomy, a normoblastic crisis. Senator¹ considers Banti's disease a splenic pseudo-leukemia.

Cases of splenomegaly, which do not present all the symptoms of Banti's disease, may probably be regarded as incipient or near forms. Gaucher has described another form of splenomegaly in which sections of the enlarged spleen revealed the presence of large endothelial cells, complexes which were also to be noted in the liver, lymph-nodes, and bone-marrow. It is doubtful, however, if this represent an independent pathologic picture, since similar cells have been found with other splenic tumors, even in Banti's disease. Clinically, cases such as Gaucher's run an extremely chronic course under the guise of an anemia with enlarged liver, but without ascites. Nägeli quotes a case of this kind described by Borissowa in which the blood resembled that of pernicious anemia (high color-index, megaloblasts, and megalocytes), except that there was a leukocytosis. The independence of this disease seems to the author just as questionable as that of the related infantile pseudoleukemic anemia.

[Bovaird² reports two cases, one with autopsy, and summarizes as follows: Splenomegaly is a definite and distinct disease; not a new growth, but an endothelial hyperplasia of the spleen associated with like changes in the lymph-nodes and the connective tissue of the liver. Brill, Mandelbaum, and Libman³ report two cases out of four occurring in one family in a single generation. They confirm Bovaird's findings.—Ed.]

THE BLOOD IN MULTIPLE MYELOMA (KAHLER'S DISEASE)

The malady was recognized as an anatomic entity before Kahler described it clinically. It is characterized by the presence of tumors in the bone-marrow, which arise from the elements of the same (*i. e.*, the myeloid, lymphoid, erythroblastic or other marrow-cells). Metastases may occur outside of the osseous system. The disease affects adults, especially men of advanced age, and is first manifested by characteristic rheumatic pains in the bones, later by progressive cachexia, nervous phenomena, and the presence of the Bence-Jones protein in the urine (p. 570 et seq.), and, finally, by spontaneous fractures, frequently an anemia of high grade, and sometimes fever. The relationship of the disease to leukemia and pseudoleukemia, *i. e.*, to lymphomatoses and blood diseases is not yet fully clear. Some such close relationship does probably exist. Pappenheim regards this malady as the myeloid analogue of lymphoid pseudoleukemia, and terms it *myeloid pseudoleukemia*. Little is known of the blood-picture. Many cases of the so-called leukanemia should perhaps be classed as Kahler's disease. The hemoglobin and the red cell count are frequently both diminished. Though the white cells do not always present abnormal changes, cases with neutrophile leukocytosis and lymphocytosis have been described. Sometimes Türk's irritation forms are found in great numbers (p. 792 et seq.).

THE BLOOD IN PURPURA

It is impossible to draw a characteristic blood-picture for this disease, since even if one exclude cases where the symptom-complex purpura develops from a well-recognized malady (nephritis, leukemia, etc.), the diseases accompanied by purpuric symptoms show no agreement in their etiology. Nägeli, in a study of several cases of so-called simple and rheumatic purpura, was unable to find any striking morphologic changes in the blood. The eosinophiles were only moderately reduced in number.

The blood in the severe form of morbus maculosus (Werlhofii) has no peculiar characteristics. According to the author's experience, these cases cannot be considered one and the same disease. They behave like infections of very different types. It must be strongly emphasized that many cases which were formerly called acute morbus Werlhofii or *purpura fulminans* are really nothing more than the most acute form of *lymphoid leukemia*. (See p. 835.) In these acute cases the swelling of the lymph-nodes is often almost, or quite, unnoticeable, so that mistakes are very easy. The author recently saw a case diagnosed as morbus maculosus Werlhofii which presented all the symptoms of the malady, but in which the diagnosis of acute leukemia

¹ Berlin. klin. Woch., 1901, No. 46, and Deut. Klinik, 1903, vol. iii.

² Amer. Jour. Med. Sci., Oct., 1900, p. 377.

³ Ibid., March, 1905, p. 491, and June, 1909, p. 849.

was established shortly before death by a blood-examination. Nägeli points out that sometimes precisely in these acute cases the lymphocytosis is not very marked, so that the diagnosis must often depend on the demonstration of *qualitative* variations in the lymphocytes, especially the presence of large lymphocytes with pale nuclei, which are usually found in acute lymphoid leukemia (p. 793), and on the demonstration of the forms with lobulated or cleft nuclei described by Rieder (p. 793). Furthermore, Nägeli calls attention to the fact that there are also cases of acute aleukemic lymphomatoses (acute lymphoid pseudoleukemia) which may resemble morbus maculosus Werlhofii throughout. Here also the demonstration of the abnormal lymphocytes mentioned above is of great importance in the diagnosis.

THE BLOOD IN SCORBUTUS AND IN BARLOW'S DISEASE

In but few cases of scorbutus has the blood been studied, and nothing characteristic has been found. Oligochromemia dependent chiefly on the degree of hemorrhage has been demonstrated. The red cells are usually less markedly decreased than the hemoglobin. In accord with other inflammatory symptoms the leukocytes are quite markedly increased (up to 60,000, Senator). Besides this, myelocytes, normoblasts, and megaloblasts are found. In any case the examination of the blood is of great aid in avoiding confusion with hemorrhagic lymphomatoses or leukemia and pseudoleukemia. Infantile scurvy (Barlow's disease) offers no more characteristic a blood-picture than scorbutus in adults. Senator (Berlin. klin. Woch., 1902, No. 20), De Bruin (Nederl. Tijdschr. von Genesk., 1902), and Wynhausen (Arch. f. klin. Med., 1908, vol. xcii), have found oligochromemia, polychromatophilia, poikilocytosis, normoblasts, and especially a relative and absolute lymphocytosis. The last, however, is present even in normal children.

THE BLOOD IN HEMOPHILIA

But few complete examinations of the blood in this disease are extant. In agreement with Wright the author found in three cases a relative lymphocytosis without any increase in the total count. This naturally means a corresponding decrease in the polynuclears. This finding, however, does not seem to be constant, since Morawitz and Lossen¹ found in one case approximately normal numbers of polynuclears and lymphocytes. Once the author found an increase in the eosinophiles, and at another time a moderate number of myelocytes. Morawitz and Lossen also found that the blood-platelets are essentially normal. On account of this practically characterless blood-picture all the more stress must be laid on the defective coagulability of the blood.² (See p. 742.)

THE BLOOD IN MYXEDEMA

J. Bence and K. Engel³ found in myxedema a relative lymphocytosis and an eosinophilia with a decrease in the absolute number of polynuclears.

THE BLOOD IN EXOPHTHALMIC GOITER

The blood-findings in this disease have only recently been described. Caro⁴ found that a marked diminution in the polynuclear leukocytes and a corresponding increase in the lymphocytes up to 50 per cent. is characteristic. The small lymphocytes predominate.

THE BLOOD IN MALIGNANT TUMORS

As is well known, malignant tumors often give rise to anemia, chiefly through the general cachexia, and the hemorrhages, sometimes, also, through the progressive destruction of the bone-marrow by metastases. This anemia is usually accompanied by leukocytosis, and, as a rule, the hemoglobin index is less than 1. Polychromatophilia and basophile degeneration of the red cells are very frequent. Nucleated red corpuscles, if present, are usually normoblasts. They may be numerous if there be metastases in the bone-marrow. Megaloblasts and megalocytes are rare. The

¹ Morawitz and Lossen, Deut. Arch. f. klin. Med., 1908, vol. xciv, parts 1 and 2.

² See p. 741 et seq. and Sahli, Zeit. f. klin. Med., 1903, vol. lvi, also Morawitz and Lossen, *loc. cit.*

³ Bence and Engel, Wien. klin. Woch., 1908, No. 25.

⁴ Berlin. klin. Woch., 1908, No. 39.

anemia may, especially in gastric cancer, reach a high grade, and may exceptionally assume all the characteristics of the pernicious type; thus the color-index may be greater than 1, the leukocytosis be replaced by leukopenia, and the normoblasts by megaloblasts. All this arises not from the occurrence of metastases in the bone-marrow, but from the gastric achylia, as in true pernicious anemia (p. 826 et seq.). Such cases have been spoken of as cancer complicated by pernicious anemia; it would seem to the author more accurate to speak of gastric carcinoma as the occasional, though rare, cause of pernicious anemia. In such cases the diagnosis between pure pernicious anemia and an anemia of pernicious type following cancer can, of course, not be made from the blood. Should there be no tumor the decisive symptoms are the bacteriologic findings in the stomach-contents (p. 477), the demonstration of stasis and of lactic acid and other signs of gastric carcinoma. Very frequently the occurrence of leukocytosis is a symptom of great weight in the differential diagnosis.

Following metastases of malignant tumors into the bone-marrow numerous large mononuclear cells have been found,¹ which Nägeli calls myeloblasts. Myelocytes also may occur, sometimes in great numbers. With extensive metastases into the lymph-nodes there may at first be a lymphocytosis; this, however, becomes less and less as the lymph-nodes are progressively destroyed, and is finally replaced by a lymphopenia. In the early stages of malignant tumors the eosinophiles may be increased; but in the cachectic stage they are, on the contrary, usually less than normal.

THE BLOOD IN PAROXYSMAL HEMOGLOBINURIA

During the paroxysms of hemoglobinuria poikilocytosis and fragmented blood-cells are found, as well as the so-called erythrocytic shadows (ghosts, see p. 785). No morphologic changes have as yet been noted during the intervals. In contrast to the old theory of periodic hemoglobinuria and to the findings in toxic or infectious hemoglobinuria, the blood-serum of the patient is free from hemoglobin during the attacks. (Demonstration of hemoglobin in the serum, p. 855.) This is explained by Choroschilow's² supposition that paroxysmal hemoglobinuria depends on a lessened resistance of the red cells to the action of cold, as, for instance, the application of cold to the body surface; but that the injured cells first yield their hemoglobin while in the kidneys, and that immediately upon its liberation it is excreted. To explain this Choroschilow further assumes that the injured cells act as a specific stimulant to the kidney, to withdraw from them their hemoglobin-content and excrete it. The harmful action of cold may best be demonstrated by drawing the blood from the finger-prick into a capillary tube, provided with an ampulla, which is immersed in iced water and allowing it to lie thus for twenty minutes. The use of the capillary tube is essential for obtaining a thin layer of blood corresponding to that in the skin capillaries. The serum expressed from the clot is colored red in contrast to the normal serum (dissolved hemoglobin). If, however, the coagulation of the chilled blood be hindered by the addition of 0.1 per cent. sodium oxalate solution, no red color is imparted to the plasma. In other words, the expression of hemoglobin in this experiment is dependent upon coagulation; whereas in vivo, it depends upon the action of the kidney. One can establish the diagnosis of this disease by performing the above experiment. During the attacks the blood clots unusually fast, but after a little time the clot is redissolved (Hayem and Chvostek).

THE BLOOD IN CHRONIC LEAD-POISONING. (SATURNISM)

The diagnosis of chronic lead-poisoning which, in doubtful, especially in medico-legal, cases formerly sometimes offered great difficulties is much easier with the aid of a blood-examination. This intoxication often gives rise to anemia, i. e., to oligochromemia, which may, however, be lacking despite the pallor of the patient. If it be present, normoblasts, anisocytosis, poikilocytosis, polychromatophilia, and, according to Grawitz, even megaloblasts may be found. There are no data concerning the color-index. [Ewing, Buchanan, Cabot, Emerson, and Nägeli all report a color-index less than 1.—Ed.] Basophilic degeneration of the erythrocytes is especially characteristic and of great importance in the diagnosis (p. 784)—all the more so if there be no very marked oligochromemia, for in other severe anemias it is usually found. Little weight should be put on isolated examples of basophile stippling, since they may be noted even in normal individuals (P. Schmidt, Rosen, and Biber, p. 784). The leukocytes are usually normal. It is not known whether or not leuko-

¹ See Schleip, Zeit. f. klin. Med., 1906, vol. lix.

² Zeit. f. klin. Med., 1907, vol. lxiv, parts 5 and 6.

penia be present in severe anemias due to lead-poisoning. Grawitz claims that myelocytes are sometimes found. Besides aiding in the diagnosis of fully developed cases, the demonstration of basophilic stippling is of use in predicting the development of the same, and, therefore, is of value in prophylaxis. In regard to the prognostic value of variations in the number of stippled red cells see p. 784.

THE BLOOD IN PHOSPHORUS-POISONING

Pisarski¹ found that in mild as well as in severe cases of phosphorus-poisoning after a longer or shorter time a transitory polycythemia supervenes (*polycythemia vera seu rubra*, p. 832), and that in severe cases there is a leukopenia affecting the polynuclear leukocytes only, which, in favorable cases, is replaced by a leukocytosis. In mild cases the leukocyte count is normal. After the poison has been eliminated, normoblasts appear.

THE BLOOD IN ICTERUS

Besides bile-pigment in the blood-serum (p. 857), crenation and lack of rouleaux formation may be noted in fresh preparations of the blood of jaundiced patients (Gerhardt). In *icterus neonatorum* O. Silbermann found megalocytes, microcytes, poikilocytes, and erythrocytic shadows (p. 785). Despite the destructive influence of the bile salts Becquerel and Rodier found an increase in the number of red cells. Observations concerning the hemoglobin content are not uniform. In severe icterus the percentage is difficult to determine because of the presence of bile-pigment. In regard to the resistance of the red cells to hemolysis in different icteric conditions and the diagnostic significance of this phenomenon see p. 768 et seq.

Georgi² claims to have found the characteristic blood-picture of pernicious anemia in a case of jaundice following cholelithiasis. This claim was, however, made at a time when the definition of pernicious anemia was not so strict as at present. This question is of considerable practical importance because there are not a few cases of pernicious anemia which are complicated by hematogenous icterus and intermittent fever. If Georgi's contention be correct, one would have to make, in such cases, a differential diagnosis between cholelithiasis and pernicious anemia. It is, however, according to the previously quoted studies, quite unlikely that a chronic obstructive jaundice can give rise to a blood-picture characteristic of pernicious anemia, because, outside of the fact that no authentic observations of such a sequence have been recorded, the red cells in the former condition show an increased, in the latter a decreased, resistance to hemolysis (p. 770). The practical significance of this is shown in the following case—that of a patient with pernicious anemia and jaundice whose gall-bladder was opened because the surgeon wrongly diagnosed a cholelithiasis on account of the icterus and the periodic rises in temperature so common in pernicious anemia, and this contrary to the advice of the attending physicians, who supported their view by careful blood-examinations, and in spite of the fact that nothing pointed to a cholelithiasis and that the temperature was not accompanied by local symptoms, but merely by an increase in the jaundice and in the excretion of urobilin.

The leukocytes vary greatly according to the cause of the jaundice. Limbeck found a leukopenia (4000 to 7000); Grawitz, sometimes a marked leukocytosis (30,000 to 40,000). Data concerning the reasons for these variations, as well as differential counts, are as yet unavailable.

THE BLOOD IN BRONCHIAL ASTHMA

While the presence of eosinophile cells in the sputum has been recognized for a long time, there are but few studies extant concerning the behavior of the blood in this disease. In general an increase in the eosinophiles has been claimed (p. 808). According to an observation made by Heineke and Deutschmann,³ there was a moderate neutrophile leukocytosis at the beginning of the attack. The number of eosinophiles rapidly dropped below normal, then rose above normal, and ultimately normal figures were reestablished. In addition, lymphocytosis was noted in connection with the attack. These observers, therefore, assume that the eosinophile cells in the sputum arise from the blood, and are not, as has been claimed, histogenetic. The nuclei of the eosinophiles in the blood were frequently but indistinctly lobulated, or were merely indented, so that it may be assumed that the mononuclear cells in

¹ Deut. Arch. f. klin. Med., 1908, vol. xciii, part 3, p. 308.

² Quoted from Grawitz, *Klinische Pathologie des Blutes*, Berlin, 1896, p. 197.

³ Münch. med. Woch., 1906, No. 17.

the sputum, the occurrence of which suggested the histogenetic theory, arise from eosinophiles in the blood which undergo secondary changes within the bronchi. (In regard to eosinophile cells in the sputum see Fuchs, *Deut. Arch. f. klin. Med.*, vol. lxiii.)

THE BLOOD IN BURNS

In three fatal cases of burns of the first to the third degrees Hedinger found peculiar malformations of the red cells, spheric forms, thick disk forms, crenation and bell shapes; also mutilated structures resembling the blood-platelets. These formations correspond to the artefacts produced by heating blood to 50° to 60° C. They agree with the older findings of Albrecht. Hedinger explains the changes by assuming a melting of the lipoids in the superficial layers of the red cells. The "platelets," which are probably not true blood-plates, may contain hemoglobin, but may also appear quite colorless.

OSMOTIC PRESSURE OR MOLECULAR CONCENTRATION OF THE BLOOD

In contrast to cryoscopy of the urine, which received a rather adverse criticism upon p. 666 et seq., we possess in cryoscopy of the blood an extremely valuable method of examination. It furnishes important conclusions, particularly in the diagnosis of functional diseases of the kidneys. It cannot be replaced by the determination of the specific gravity of the blood-serum, since to get results analogous to those obtained from the osmotic pressure the albumin must be removed from the blood-serum, and the complete removal of so large a quantity of albumin is possible only after a preceding dilution. Moreover, in view of the small quantities of blood usually at our disposal, the specific gravity must be determined by the rather troublesome capillary-pyknometric method of Hammerschlag. (See p. 735.)

The nature of the osmotic pressure and its measurement by determinations of the freezing-point, or cryoscopic examination, have been explained on p. 662 et seq. In reference to the technic the reader is also referred to what has previously been stated in detail (p. 663 et seq.). Only those features which are peculiar to the cryoscopy of the blood will now be discussed.

The determination of the freezing-point of the blood is usually carried out by withdrawing rather a large quantity of blood (usually about 20 cc.) from the patient by venesection (see p. 731) and allowing it to coagulate. The separation of the serum from the clot may be accelerated by loosening the latter from the sides of the vessel. This serum is then employed for the examination. The freezing-point, or osmotic pressure, of the serum is practically equal to that of the plasma, because fibrin, in consequence of its great molecular weight and of the small percentage present, exerts practically no influence upon the lowering of the freezing-point. Since the osmotic pressure of the serum is equal to that of the plasma, it must also be equal to that of the whole blood or of the defibrinated blood, since the blood-corpuscles must necessarily possess the same osmotic pressure as that of the plasma. It consequently follows that the osmotic pressures of the serum, of the plasma, of the whole blood, and of the defibrinated blood are identical. Nevertheless, we do not recommend the employment of the whole blood unless hirudin has been added, because it can be used only after coagulation, and with this semi-solid mass, even though it be stirred, we have no guarantee that the temperature is absolutely homogeneous. It is only when a sufficient quantity of serum cannot be obtained that the coagulated whole blood may be employed, and then it should be well broken up by the platinum stirrer after its introduction into the freezing apparatus and before the determination is made. It is better previously to defibrinate the blood. This may readily be accomplished immediately after its withdrawal by stirring it in a glass vessel for some time with the platinum stirrer belonging to the freezing apparatus. In every case all the hemoglobin should be changed into oxyhemoglobin before coagulation and separation of the serum, since the blood obtained by venesection always contains a large quantity of CO₂, and since the variable quantities of CO₂ found combined or free in the blood are dependent upon the degree of oxidation of the hemoglobin, so that this naturally has some influence upon the osmotic pressure. Besides this, anions go over from the plasma into the corpuscles where the blood is rich in CO₂. (See p. 851.) Constant results will be obtained only when the blood employed is saturated with oxygen. This saturation with oxygen is most easily insured by allowing the blood from the cannula to trickle in a thin layer along the sides of the receiving vessel. The contact of the blood with atmospheric air is sufficient to convert all its hemoglobin into oxyhemoglobin; the area of contact may be increased by catching the blood in a funnel

introduced into the mouth of the receiving vessel, and then markedly tilting the funnel so that the blood will spread out in a thin layer upon its inner surface and trickle slowly into the receptacle. Where the blood has been defibrinated, the stirring necessary for that purpose is sufficient to convert the reduced hemoglobin into oxyhemoglobin. Some investigators also pass oxygen into the blood, but this seems superfluous to the author and too complicated for clinical purposes. It might also be noted that it does not matter whether or not some of the erythrocytes remain in the serum (as frequently happens), since defibrinated blood and serum have the same freezing-point.

The normal freezing-point of the blood is -0.56°C ., corresponding to that of 0.9 per cent. NaCl solution.

The most important result of the determination of the freezing-point of the blood is that it gives definite information in reference to the sufficiency or insufficiency of the elimination of urinary solids by the kidneys. When the method is accurately carried out with due regard to the previously mentioned precautions, among which the author would lay special stress upon the saturation of the blood with oxygen, a depression of the freezing-point amounting to 0.01° to 0.02° must be regarded as pathologic. Considerable elevations of the osmotic pressure of the blood are most frequently encountered in uremic conditions when freezing-points of -0.65° and -0.7°C . are by no means rare. This evident disturbance of the elimination of urinary solids undoubtedly has some relation to uremia; but the idea that an elevation of the osmotic pressure is constantly present in uremia is incorrect, as is also the converse—that uremic symptoms must be present when the osmotic pressure is increased. From this it follows that uremia is not dependent upon the elevation of the osmotic pressure alone, but must be due to the retention of some special substances.¹ This retention cannot be recognized from the freezing-point of the blood when the retained substance is compensated for, from an osmotic standpoint, by the elimination of other solids. Disregarding the question of uremia, the determination of the freezing-point of the blood furnishes the most important data for the estimation of the work done by the kidneys in a given case of nephritis, and consequently justifies important conclusions in reference to treatment. The author would call special attention to the fact that, while all conclusions in reference to the renal function based upon cryoscopic examination of the urine are inaccurate except in extreme cases, a renal insufficiency may be surely concluded from a distinct elevation of the osmotic pressure of the blood, and this must be considered in deciding for or against unilateral nephrectomy, though, to be sure, more recent experiments have shown that a moderate depression of the freezing-point of the blood does not always contraindicate this operation.

Very considerable elevations of the osmotic pressure of the blood have also been observed in cardiac cases with broken compensation.² Since uremic symptoms, in the ordinary sense of the word, are scarcely ever present in these cases, it follows that uremia does not essentially depend upon the elevation of the osmotic pressure of the blood.

The osmotic pressure of the blood may be lowered in the retention of water as the result of nephritis, in case this retention is not compensated for from an osmotic standpoint by the simultaneous retention of urinary solids, as is usually the case. If the loss of osmotic pressure be more than compensated, cryoscopy is of no value for the recognition of hydremic plethora, and we must then employ what is really the best method for this purpose, the determination of the relative quantity of hemoglobin in the blood. (See p. 731.)

The lowering of the osmotic pressure of the blood indicative of the retention of water in febrile diseases is also of general pathologic interest.³

INVESTIGATION OF THE VISCOSITY OR OF THE INTERNAL FRICTION OF THE BLOOD

The clinical importance of the determination of the viscosity of the blood rests upon the fact that, according to the laws of Poiseuille and Hagen concerning the flow of liquids through capillary tubes, this quality is an essential factor in determining the velocity of the blood-current. From the physicochemical investigations of

¹ From the constant findings of Strauss in his analyses of the blood in uremia these retained substances are nitrogenous, and consist largely of urea.

² Landau, Arch. f. klin. Med., 1904, vol. lxxviii.

³ See Landau, *ibid*.

Ostwald¹ and the physiologic study of the question by Hürthle,² C. Hirsch and C. Beck³ have worked out a clinical method for determining at the bedside the viscosity or internal friction of the blood. The apparatus employed is illustrated in Fig. 314. The method depends upon measuring the time required by a known quantity of blood to flow through a capillary tube under a definite pressure. The experiment must be carried out at a constant temperature, since the temperature influences the viscosity. The apparatus⁴ is constructed as follows: It consists of the hand-bulb *A*, of the calcium chlorid tube *B*, of the pressure flask *C*, which is protected against heat-conduction and radiation by a felt jacket; of the manometer *D*, which is rendered more sensitive by being filled with benzol; of the water-bath *E*, and of the actual measuring apparatus *F*. This measuring apparatus consists of a U-shaped tube, *XV*, which is dilated at *G*, below which it becomes capillary, to dilate again at the bend *U*, and pass into the ampulla *M*, in which the closed tube *V* is inserted by means of a ground joint. There is a mark both above and below

Fig. 314.—Apparatus of C. Hirsch and C. Beck for the determination of the viscosity of the blood.

the dilatation at *G*. The capacity of *G* is about $\frac{1}{4}$ cc., and the diameters of the different capillary tubes vary between 0.25 and 0.35 mm. During the course of the experiment this measuring apparatus is held by a support, as indicated in the figure, immersed in a water-bath at a temperature of 38° C., and connected by the T-tube *T* and tubing with the pressure flask *C*, the calcium chlorid tube *B*, the hand-bulb *A*, and the manometer *D*, as indicated in the illustration. The upper end of the closed tube of the measuring apparatus projects into the air above the level of the water. Before commencing the experiment, the measuring apparatus should be kept for some time in air at a temperature of 38° C., so that we may be certain that its temperature is 38° C. immediately after its immersion in the water. Beside the appa-

⁴ Made by C. Desaga, Heidelberg.

ratus is a stop-watch which registers fifths of a second. The experiment now proceeds as follows: The connection is broken at *P*; the tube leading to the pressure flask is closed by a stop-cock, and the desired pressure of 400 mm. of water, equal to 452 mm. of benzol, is obtained in the pressure flask by means of the hand-bulb. The U-shaped lower portion of the measuring apparatus is now filled to the upper end of the ampulla (*M*) with blood, which is obtained fresh from an exposed vein in the arm by means of a pointed and bent glass cannula or the sharp metal cannula mentioned on p. 731. If the latter be used, it is not necessary to expose the vein, though this procedure has the advantage that the blood can be obtained without the production of artificial stasis. The closed tube *V* is now quickly inserted. Suction is then made at *Z* until the blood is just above the mark *X*. The measuring apparatus is now connected with the pressure flask by the glass tube *Z P*. The stop-cock is opened so that the pressure forces the blood downward through the capillary tube. The stop-watch is set going as soon as the upper level of the blood-column passes the upper mark *X*, and is stopped at the moment when it reaches the lower mark *X*. The experimenter notes the elapsed time, convinces himself that the pressure has remained constant, and immediately repeats the measurement. In this manner from two to six measurements may be made with the same blood. The manipulation must be done very quickly, so that it may not be interfered with by coagulation. According to Jakoby,¹ blood may be employed which has been rendered non-coagulable by the addition of leech extract or hirudin. This does not influence the result, while defibrinated blood exhibits a diminished viscosity. This procedure has been used in the author's clinic with success. The addition of hirudin facilitates the estimation of the viscosity, for one is not compelled to hurry. One mg. of hirudin is sufficient to prevent the coagulation of 5 cc. of blood. The apparatus is cleaned with soda solution and distilled water and kept in a dry place.

The necessary calculation is made by the formula—

$$n = n_1 \frac{st}{s_1 t_1},$$

in which *n* is the desired coefficient of the internal friction of the blood, *s* the specific gravity of the blood, *n*₁ the coefficient of the internal friction of the fluid with which the blood is compared, *s*₁ the specific gravity of this fluid, and *t* and *t*₁ the flowing-times of the two fluids. Freshly distilled anilin is selected for comparison, since its specific gravity is so close to that of the blood that it may be assumed to be equal to it. This simplifies the formula, so that—

$$n = n_1 \frac{t}{t_1}.$$

It also appears to the author that in the Hirsch-Beck method, where, in contrast to Ostwald's, gravity is not a factor, the specific gravity must be left out of the equation.

*n*₁, the coefficient of viscosity of anilin, is compared with that of water (which serves as the unit in these investigations), is determined once for all, and it consequently follows that, in order to calculate *n*, we must simply determine the flowing-time of anilin = *t*₁. We then know the value of *n*₁ and *t*₁, and, as we have determined *t* for the blood, the formula gives us the value *n*; that is, the coefficient of the viscosity of the blood as compared with water. Since interest centers chiefly in relative values, it is still simpler for clinical purposes to select the viscosity of anilin as the unit. This gives us—

$$n = \frac{t}{t_1}.$$

In order to obtain the coefficient of water from this, one must multiply *n* by the coefficient of anilin compared to water. According to Hirsch and Beck, this is about 3.75. Since the foregoing study, still other methods for determining the viscosity of the blood have been devised. The following are the best known.

The viscosimeter of Robert-Tissot² is based on another principle. The viscosity

¹ Sitzung der medic. Gesell. in Göttingen, January 10, 1901. Ref. in Deut. med. Woch., 1901, No. 8.

² Folia Hematologica, 1907, vol. iv, part 4.

of the blood is estimated by determining the decrease in the amplitude of oscillation of a gold-plated metallic cylinder suspended in blood, which has been rendered non-coagulable by means of hirudin. The cylinder of a Pravaz syringe with which the blood has been withdrawn serves as the containing vessel after the plunger has been removed, the point of the syringe being closed with a rubber cap. The cylinder is warmed to 38°C . before the blood is withdrawn, and during the experiment is kept in a chamber heated to this temperature.

*The Viscosimeter of W. Hess.*¹—Hess uses, as do Ostwald, Hirsch, Beck, Determann, and others, the rate of flow of blood through a capillary tube, but with the difference that he does not determine the relation of the flow for a given amount of blood to the same amount of water, but the relation of the amounts of water and of blood flowing for a given interval of time. No hirudin is used.

The description of the apparatus and the method is given in the author's words.

"On an opalescent glass plate *H* are fastened two graduated tubes (Fig. 315), *A* and *B*, both of which communicate, on the one hand, with the tube *G*, and, on the other, with the bulb *L*, by means of the rubber tube *K*.²

"The two tubes are narrowed at the other end into capillaries, *C* and *D*, having a very fine bore. Further on they widen out into tubes *E* and *F* of the same caliber as that of *A* and *B*. The tube *F*, which fits on *H*, is held in place by the spring *N*. This tube can be removed, and can be replaced by other tubes of similar dimensions. By means of the stop-cock *Q* one is able to bring *B* into communication with *G* and to cut off the communication with the bulb *L*. The tubes *A* and *B* are bent at right angles before they communicate with *G*, so that they, with the tube *K*, enter the tube *G* from above. Between the tube *K* and the bulb *L* is interposed a piece of glass tubing *V*, in which is a small hole which permits communication of the system of tubes with

Fig. 315.—Viscosimeter of Hess (seen from above).

the air. The plate *H* is fastened in a case which contains all the other parts of the apparatus, tubes to replace *F*, a bottle of ammonia, a thermometer, etc. The dimensions of the case are $27 \times 9 \times 6$ cm.

"The determination is carried out in the following way: In the tubes *B*, *C*, and *E* is placed a column of water so that the left end of the column is exactly at the zero mark of the scale. The stop-cock is closed and so shuts off communication of the system *B C E* with the bulb *L*. Before the tube *F* is placed in position, it is filled with a drop of blood which is run in by capillary attraction. After placing in position, the blood is sucked into the capillary tube and into the tube *A* by means of the bulb, *L*. When the blood has reached the zero point in the tube *A*, as is shown in the figure, the stop-cock *Q* is turned, and the bulb is, therefore, in communication with the system *B C E*. By further suction *B* is filled with water from *E* through the tube *C*, while at the same time blood flows into *A* under the same pressure. As soon as the latter has reached the mark 1, the pressure is removed by releasing the finger from the opening *P*, so that both water and blood remain stationary. The amount of water which has flowed into the tube *B* can be read off on the scale and this shows the relative viscosity of the blood to the water. By pressing the bulb *L* both water and blood are driven back. When the former has reached the zero point, one closes the stop-cock *Q* and empties the blood completely from *A* and *D*. The tube *F* is

¹ Münch. med. Woch., 1907, No. 45.

² The bulb *L* is used for pressure and for suction. Pressure is obtained by closing the hole *P* with the finger and pressing the bulb. Suction is obtained by pressing the bulb and then closing the hole *P*. When the pressure is released from the bulb, suction is produced. By removing the finger from the hole both pressure and suction are stopped.

removed and is replaced for the next experiment by a fresh one. By washing out *D* and *A* twice with ammonia the apparatus is ready for another experiment."

The principal objection which can be raised to the apparatus of Hess is that the action of the ammonia remaining in the apparatus may change the viscosity of the blood. This is not the case, for the blood which comes in contact with the ammonia solution is not used for the determination of the viscosity. That part of the blood which is contaminated with ammonia at the time the blood is placed at zero has left the capillary and is to be found in the shaded part of the tube *A*, where, owing to the relatively wide caliber of the latter, it does not influence the viscosity. In other words, in setting the scale, the ammonia is removed from that part of the apparatus which is used for the determination of the viscosity, so that the blood used for this purpose may be regarded as free from ammonia.

The tubes *F* are washed out, and allowed to stand in ammonia. When a number of them are used up, they are dried by heating them on a metal plate. One may avoid cleaning them by purchasing a large number and throwing them away after once using. Their cost is nominal.

If a sample of blood be very viscous, it is sucked up only to the mark $\frac{1}{2}$ or $\frac{1}{4}$, and the results multiplied by 2 or by 4.

Control tests with the apparatus with fluids of known viscosity give an error within 1 to 2 per cent.

Hess found that on raising the temperature 1 per cent. the viscosity decreased 0.8 per cent., so that tests which are performed at room temperature may have an error of about 4 per cent. According to Hess, such an error may be neglected when the variations which are found in pathologic conditions are taken into consideration. He considers that a temperature correction is only necessary where the temperature difference is considerable.

The mathematic and physical principles for the method are given in Hess' paper (*Vierteljahrschr. der Züricher Naturforsch. Gesellschaft*, Jahrg. 51, 1906¹).

Hess found that the value at 37° C. was about 17 per cent. lower than at 17° C. If one wish to reduce the value to the temperature 17° C., one must subtract 0.8 per cent. for every degree above this temperature. The estimations which are made at room temperature, however, give sufficiently accurate values for clinical purposes, and may be used without recalculation.

On the other hand, Hess has found that the withdrawal of the blood must be done with certain precautions, for if this be not done, the values with the same individual may vary as much as 8 per cent. This is not due to any inherent defect in the method, but to the fact of varying conditions of circulation at the point of withdrawal. Hess found, as have others, that local venous stasis may increase the viscosity. Massage of the skin decreases the viscosity. In order to make the conditions as comparable as possible, Hess recommends that the patient place the finger in warm water and massage it well in drying it. The values so obtained are nearly those of arterial blood.

Concerning the clinical value of viscosity determinations one must concede that the practical results are so far not altogether certain. The older investigations are contradictory, due to the fact that most of the determinations were performed with blood which was removed from a vein in the arm during marked venous stasis. According to the degree of stasis, the results are invalidated to an extent which cannot be estimated. Although stasis raises the viscosity, the values found may lead to errors in both directions because stasis may act more in one case than in another, and one may observe a decrease in the relative viscosity of one case to another when there is actually an increase. Since no estimations of the viscosity of blood taken from a vein in the arm, with the exception of those where the vein has been exposed (p. 848), are free from the above objections, both the methods of Hess and of Determann, which use a small quantity of blood, taken either from the ear or from the finger-tip, represent a distinct step forward.

A necessary condition for the clinical use of the determination of the viscosity of the blood is some knowledge of the normal relations of the viscosity and of the changes under physiologic conditions. F. Blunschy,² under the direction of Hess, has recently given some information on this subject.

The principal results of the investigation with Hess' method are as follows: The diurnal curve for the viscosity of the blood shows a curve which falls from 8 A.M., rising toward 9 P.M. The minimum is found between 2 and 6 P.M. The

¹ The apparatus is to be obtained from J. G. Cramer, Glasbläserei, Spiegelgasse 7, Zürich, 1. The price is 32 Marks.

² I. A. D., Zürich, 1908, Beiträge zur Lehre von der Viscosität des Blutes.

morning maximum at 8 A. M. varies between 5.68 and 4.41; the minimum in the afternoon can sink as low as 3. It is remarkable that the increased viscosity is due to assuming the erect position, because, after rising, the viscosity goes up sharply, and then commences to fall, while persons who remain in bed do not have the fall during the morning. The intake of food and fluids decreases the viscosity, as does moderate bodily exercise. Violent exercise increases the viscosity (due to perspiration). Alcohol and caffein increase the viscosity; coffee decreases it, as does camphor. Digitalis administered to healthy subjects is without effect. In general disturbances of the circulation and the respiration Blunschy found, as have other observers, that viscosity is increased. Inhalation of oxygen decreases the viscosity. This agrees with Hamburger's observations¹ that increased content of the blood in carbon dioxid produces profound chemical changes, as the osmotic pressure of the corpuscles increases, due to the passage of anions into them from the plasma. They, therefore, increase in size. This naturally produces an increase in the viscosity of the whole blood.

Somewhat far-reaching conclusions have been drawn from the fact that the viscosity of the blood increases with increased content in carbon dioxid, and with better aëration the viscosity decreases. There can be no doubt that the general condition of a patient suffering from the increased viscosity of the blood acts as a hindrance to the circulation. If one wish to use these facts clinically, one must not forget that one cannot use the determination of the viscosity of the blood to diagnose a functional disturbance of circulation, for primary disturbances of the respiration act on the viscosity of the blood in precisely a similar way. One must also remember that local changes in the circulation may, through their influence on the distribution of the blood-corpuscles, affect the viscosity. (See p. 850.) Hess has shown how one may avoid the last error. (See p. 850.) Of the other important results which have been furnished by Hess, one may add that the assumption that the heart changes which are observed in nephritis are due to an increased viscosity of the blood has been confirmed neither by Hess, Hirsch and Beck, nor by other authors. Kottmann (*loc. cit.*) found that the viscosity of the plasma was increased in nephritis, but this cannot be considered as a hindrance to circulation as long as the total viscosity of the blood is not increased. Potassium iodid decreases the viscosity.² The viscosity is decreased in anemia.³ Cold baths and electric sweat baths increase, warm baths decrease, the viscosity (Determann, *loc. cit.*). Polycythémias increase the viscosity markedly (Kottmann, *loc. cit.*). Leukemia with marked increase in leukocytes increases the viscosity if the number of erythrocytes be not decreased sufficiently to compensate.

The viscosity after meat feeding is greater than with a vegetable diet (Determann, *loc. cit.*). After the intravenous injection of saline solution and after the withdrawal of blood the viscosity decreases. It has been generally assumed, and the assumption has been confirmed directly by Blunschy, that the viscosity of the blood is principally due to the number and size of the formed elements, especially of the erythrocytes.⁴ The investigation of the plasma gives much smaller variations.

As average values for the viscosity of the blood compared with water, Hirsch and Beck (without hirudin, blood at 38° C., water at 38° C.) give 5.1. Kottmann (hirudin, venous blood, blood at 38° C., water at 38° C.) gives 5.1. Determann (hirudin capillary blood, blood at 38° C., water at 38° C.) gives for men 4.798; for women, 4.516. As normal average values for his method and for room temperature, 20° C., Hess⁵ gives the value 4.57; for men, 4.3 to 5.3, and for women, 3.9 to 4.9. Hess has obtained a quotient by dividing the relative hemoglobin value by the viscosity. The result is a number which varies between 17 and 21, but which is mostly in the neighborhood of 19. In pathologic conditions he finds variations from this number.

The present condition of the subject of the viscosity of the blood has been brought together by J. Heusler in a recent dissertation (Zürich, 1908). The literature on the subject is given there.

¹ Osmotischer Druck und Ionenlehre, 1902.

² Poiseulle, Ann. de chimie et de physique, 1847. According to this author sodium iodid does not act in this way. See Müller and Inada, Deut. med. Woch., 1904; Kottmann, Korrespondenzbl. f. Schweiz. Aerzte, 1907, Nos. 4 and 5.

³ Determann, Zeit. f. klin. Med., 1906; Kottmann, *loc. cit.*

⁴ Besides the excess of carbon dioxid, this is perhaps another and more important reason why one finds too high values for the viscosity of the blood when the blood is taken from an occluded vein.

CHEMICAL EXAMINATION OF THE BLOOD

(Percentage of hemoglobin, see p. 742. Reaction of the blood, see p. 736. Removal of the blood for the purpose of chemical examination, see p. 731.)

IRON TESTS FOR THE BLOOD WITH JOLLES' FERROMETER

A. Jolles¹ has devised a method for determining the amount of iron in the blood by means of an instrument called a ferrometer.² The method requires only small amounts (0.05 cc.) of blood. Its principle is, briefly, as follows: A measured quantity of blood (0.05 cc.) is removed with a special capillary pipet (such as is used in Gowers' hemoglobin examination, p. 744). It is reduced to an ash in a platinum dish, 0.1 of acid potassium sulphate is added, and the mixture is heated and evaporated to dryness. The residue contains the iron of the blood in the form of an oxid of iron. This is dissolved in 10 cc. of hot water and 1 cc. of diluted hydrochloric acid (1 in 3), and 4 cc. of ammonium thiocyanate solution (7.5 : 1000) added, so that the total quantity is 15 cc. This gives the red solution of ferric thiocyanate, whose composition can be determined colorimetrically by comparing it with a solution containing a known quantity of iron. The latter is prepared in such a way that each cubic

centimeter contains exactly 0.00005 of iron.³ One cc. of this standard solution is diluted to 10 cc. with water, and then 1 cc. of dilute hydrochloric acid and 4 cc. of ammonium thiocyanate solution are added just as above. The resulting solution is then, by means of the apparatus pictured in Fig. 316, compared colorimetrically with the ferric thiocyanate solution derived from the blood. This apparatus consists of two glass cylinders, *C* and *C'*, of exactly equal caliber, *C* containing accurately 15 cc., and *C'* about 16 cc. Both cylinders are subdivided into 0.1 cc., and both are closed at the bottom with glass plates, through which light is reflected from the plaster-of-Paris reflector *R*, in the direction of their axes. The ferric thiocyanate solution prepared from the blood is exactly 15 cc., and so just fills the cylinder *C*, which is then covered with a glass disk, care being taken to avoid the formation of air-bubbles. Fifteen cubic centimeters of the ferric thiocyanate solution (prepared from the stock solution) are placed in cylinder *C'* for comparison. To avoid the development of a meniscus, which will disturb the reading, a floating stopper, made of aluminum and closed at both ends with parallel glass plates, is placed on the surface of the fluid in cylinder *C'*, avoiding air-bubbles. A flat fluid surface

Fig. 316.—Jolles' ferrometer.

is thus obtained. This contrivance always displaces a slight amount of fluid, which is the reason why cylinder *C'* must be made somewhat taller than *C*. Cylinder *C'* is provided with a lateral escape stop-cock, *H*. Both cylinders can be easily removed from the base of the instrument for cleansing or filling. The tin jacket surrounding the cylinders shuts out any lateral illumination. The colorimetric comparison is made as follows: Both cylinders are filled as just described, and then the fluid in *C'* is allowed to escape through the stop-cock *H* into the vessel *A* until the contents of both tubes, as seen from above by transmitted light, present exactly the same shade. When this point is reached, cylinder *C'* is removed and the level of the fluid noted. If the amount of fluid remaining in *C'* to the base of the floating cork were exactly 15 cc., the amount of blood used (0.05 cc.) would contain 0.00005

¹ Deut. med. Woch., 1897, No. 10; *ibid.*, 1898, No. 7, and Pflüger's Arch, vol. lrv.

² Made by C. Reichert, Wien, Bannogasse.

³ For the exact steps see above reference. The fluid may be obtained from the manufacturer of the instrument.

of iron, *i. e.*, 1 liter of blood would contain 1 gm. of iron. If, however, when the color in the two cylinders is alike, *C'* contain only 7.5 cc. of fluid, the amount of iron contained is only half as much, *i. e.*, 0.5 gm. per liter of blood. A table to calculate the percentage of iron contained in the blood has been prepared by Jolles, and is included with the instrument. It takes about ten to fifteen minutes to estimate the amount of iron with Jolles' ferrometer.

The same maker (Reichert) has recently placed upon the market an instrument which may be used either as a Fleischl-Miescher hemometer or as a Jolles' ferrometer, since the intensity of the color of the ferric thiocyanate solution is estimated by means of the glass wedge of the hemometer.¹

Jolles believed at first that his method was an accurate means of determining the amount of hemoglobin indirectly, for he assumed that hemoglobin contained 0.42 per cent. of iron, and that all the iron present was contained in the hemoglobin. But in more recent communications² he has abandoned the theory, as his investigations have led him to conclude that the blood contains considerable quantities of iron, probably in the shape of nuclein, outside of the hemoglobin. This idea corresponds to the views of Biernatzki and Jellinek. Moreover, it is likely that hemoglobin itself does not always contain a constant amount of iron. The great variations (which have been reported) as the result of analyses of hemoglobin crystals in one and the same animal species would seem to suggest this.

Although these statements might seem to imply that the estimation of the iron in the blood might acquire a clinical significance independent of that of the estimation of the hemoglobin, the investigations of Krüss³ and Schwenkenbecher⁴ would make this seem very doubtful, since these writers reached the conclusion that the double ferric thiocyanate producing the red color in Jolles' method becomes so markedly dissociated by dilution that the red color decreases in intensity more rapidly than does the quantity of iron in the solution. In other words, iron cannot be accurately estimated by this colorimetric method.⁵

ESTIMATION OF THE AMOUNT OF ALBUMIN IN THE BLOOD, ACCORDING TO DEYCKE AND IBRAHIM

The method, the details of which will be found in the original paper (*Zeit. f. klin. Med.*, 1906, vol. lviii, Nos. 5 and 6) is a modification of the titration method of Denigés for the determination of albumin in the urine.

THE ESTIMATION OF THE AMOUNT OF GLUCOSE IN THE BLOOD

The detection of glucose in the blood is simple, if one remove the albumin by the method given under the uric-acid estimation (p. 855). In the filtrate the presence of sugar can be demonstrated by the ordinary reactions (p. 586). The filtrate can also be used to determine the amount of sugar quantitatively. For this purpose the author's modification of Pavy's method is useful. (See p. 620.) According to Claude Bernard, the removal of the albumin may be effected by adding to the blood an equal weight of sodium sulphate, boiling and filtering the mixture. Pavy removes the albumin by allowing the blood to run into 20 times its volume of absolute alcohol, filtering, and evaporating the filtrate as nearly as possible to dryness. The residue is dissolved in a volume of water equal to that of the blood used. The amount of glucose may then be determined by any of the methods, including that of Pavy, and the accurate fermentation saccharimeter (p. 624 et seq.).

The staining reaction which diabetic blood gives with methylene-blue may be mentioned here. Brehmer⁶ stains dried preparations of blood which have been prepared by the method given on page 773, and which have been fixed by heating for ten minutes at 135° C. with a 1 per cent. aqueous solution of methylene-blue. Diabetic blood remains almost unstained by the treatment or takes on a bluish-

¹ S. Jolles, *Berlin. klin. Woch.*, 1899, No. 44, p. 965.

² *Loc. cit.*

³ *Colorimetrie und quantitative Spectralanalyse in ihrer Anwendung auf die Chemie*, Hamburg and Leipzig, 1891, p. 176.

⁴ *Arch. f. klin. Med.*, vol. lxxv, parts 3-5.

⁵ [The objections to the procedure of Jolles have been overcome by Marriott and Wolf, *Jour. Biol. Chem.*, i, 451, 1906. This method consists in performing the reaction in acetone in the presence of ammonium thiocyanate in large excess. The determination of iron in blood and tissues by the colorimetric method is then of great accuracy.—C. G. L. W.]

⁶ *Centralbl. f. inn. Med.*, 1897, No. 22.

green tinge, while normal blood is stained intensely blue. Many other stains show a similar difference between diabetic and normal blood. The Brehmer reaction is also to be found in leukemia, nephritis, and multiple neuritis. If, by means of a proper diet, the urine become free from sugar, the staining reaction is not observed. Williamson¹ gives another reaction with methylene-blue, which obviously has nothing in common with the Brehmer reaction. It depends on the reducing action of glucose on methylene-blue. To 40 c.mm. of water, measured with the hemometer capillary pipet (see p. 744), 20 c.mm. of blood from the finger, 1 cc. of a 1:6000 methylene-blue solution and 40 c.mm. of sodium hydroxid solution of the pharmacopœia are added. The mixture is heated in boiling water for three to four minutes without shaking. If the blood be that of a diabetic, the mixture loses its color, while with normal blood the blue color persists.

THE BLOOD IN CARBON MONOXID POISONING

In marked cases of carbon monoxid poisoning the naked eye can probably appreciate the change of color in the blood. It is noticeably bright red, and almost fails to exhibit the difference between venous and arterial blood. The presence of carbon monoxid in the blood is demonstrated usually by means of the spectroscope. (See p. 544 et seq.) If a few drops of blood containing carbon monoxid be diluted with water, the mixture will show in the spectroscope two bands, between the green and yellow, very much like those of oxyhemoglobin (Fig. 233, 1). They are, however, very slightly nearer the violet end of the spectrum. They differ from the oxyhemoglobin bands by not disappearing upon the addition of ammonium sulphid, whereas the oxyhemoglobin bands are replaced by a simple band of reduced hemoglobin (Fig. 233, 2). Oxyhemoglobin bands disappear very slowly after adding ammonium sulphid to the blood, and may be temporarily reproduced if the liquid be shaken with air, owing to the concentrated action of the oxygen.

Another test for carbon monoxid in the blood consists in adding a little 10 per cent. caustic soda or potash solution to the blood contained in a porcelain dish, and then gently warming. If carbon monoxid be present in any appreciable quantity, the mixture will become very brilliant red, while normal blood will turn to a dirty greenish brown.

v. Horszkiewicz and Marx (Berlin. klin. Woch., 1906, No. 35) have very recently proposed the following test, which so far has not been used clinically. The blood is mixed with an 8 per cent. solution of quinin hydrochlorid in the proportion of 2 : 4 (2 cc. of blood to 4 cc. of quinin solution). The mixture is heated with a gas-flame until it boils. After cooling so that the mixture can be shaken without discomfort, 2 or 3 drops of fresh ammonium sulphid solution are added and the mixture shaken well. Blood containing carbon monoxid gives a bright carmin-red color, while normal blood treated in this way is a dirty brownish green.

It is advisable to perform both spectroscopic and chemical tests and compare them with the normal blood for a control, because when only a slight amount of carbon monoxid is present in the blood, quantitative differences are important in forming an opinion.

We must not overrate the diagnostic value of these investigations. The human body reacts so intensely to carbon monoxid gas that symptoms of poisoning may be very pronounced without its being possible to demonstrate the presence of this poison in the blood either chemically or spectroscopically. The author has observed such cases. In any case an examination which is not carried out immediately after the intoxication may fail, if the poisoning has not been too severe, for in these cases the carbon monoxid is rapidly carried away by the lungs.

¹ Lancet, 1900, August 4.

THE BLOOD IN METHEMOGLOBINEMIA

The blood contains methemoglobin in various intoxications, especially those due to chlorate of potash and antifebrin. Its presence is demonstrated by means of the spectroscope after sufficiently diluting the blood with water. (See Fig. 233, 3.)

THE BLOOD IN HYDROGEN SULPHID POISONING

In severe cases the color may be a dirty green, and may show the characteristic bands of sulphohemoglobin, besides the oxyhemoglobin bands. The former resemble the bands of methemoglobin, but are situated a little more toward the violet end of the spectrum (Fig. 233, 3).

THE BLOOD IN HYDROCYANIC ACID AND POTASSIUM CYANID POISONING

A small amount of the blood is dissolved in water, and dilute potassium ferricyanid added. Normal blood becomes brown, owing to the formation of methemoglobin. Blood containing hydrocyanic acid remains red. (Formation of cyanmethemoglobin.) A control reaction should be carried out with normal blood.

DEMONSTRATION OF HEMOGLOBIN IN THE BLOOD-SERUM

Hemoglobinuria may appear independently as the so-called periodic hemoglobinuria (Lichtheim), or especially in certain kinds of poisoning (potassium chlorate, toluylendiamin, nitrobenzol, truffles) and after burns. It is always produced by the solution of red blood-corpuscles within the vascular system. Hemoglobinuria is, therefore, usually associated with hemoglobinemia or methemoglobinemia. An exception is found in the periodic or paroxysmal cold hemoglobinuria in which the serum does not contain hemoglobin. The reason for this exception is discussed on page 843. Free hemoglobin and methemoglobin can be readily demonstrated in the blood by allowing several cubic centimeters of blood to coagulate. Under normal conditions the serum will only be stained slightly yellow (lutein), provided that the blood-clot has not been interfered with mechanically. In hemoglobinemia, on the other hand, the serum will be more or less of a ruby red, owing to the presence of hemoglobin in solution; or brown, if methemoglobin be present. The serum, however, must be absolutely clear, for if it be cloudy, the color may be due to an admixture of blood-corpuscles with the serum, from some disturbance during coagulation. In doubtful cases the microscope will decide the question. The stained serum will give the characteristic bands of oxy- or methemoglobin, one or both, in the spectr scope (Fig. 233, 1 and 3). The characteristics of the blood in periodic or paroxysmal hemoglobinuria are given on page 843.

PRESENCE OF URIC ACID IN THE BLOOD

Physiologically, the blood does not contain any appreciable quantity of uric acid. In chronic nephritis and acute articular rheumatism mere traces only have been found; but in gout, at least in the early stage of the attack, the amount of uric acid contained in the blood is so considerable that Garrod¹ devised a comparatively simple method, the so-called thread test, to demonstrate its presence.

According to Garrod, 30 to 35 cc. of blood are allowed to coagulate; 10 cc. of the serum which accumulates during the next few hours over the clot is mixed with 100 cc. of acetic acid.² A fine linen thread³ is placed in the mixture, which is then covered so as to prevent evaporation, and allowed to stand.

If the blood contain at least 0.0025 per cent. of uric acid, characteristic crystals (Fig. 253) will appear on the thread in the course of one or two days. In doubtful cases the murexid test (p. 673) may be applied to these crystals.

Garrod indirectly demonstrated an increase of uric acid in the blood in gout by performing this test with the serum of an artificially produced blister.

Garrod has been able to demonstrate the increased uric-acid content of the blood in a more satisfactory manner. The blood is allowed to clot, and 60 cc. of the serum is dried on the water-bath. The dried residue is pulverized, and extracted with boiling alcohol, and the extracted powder is then treated with boiling distilled

¹ A. B. Garrod, Gout and Rheumatic Gout, London, 1876.

² Thirty per cent. solution according to Minkowski.

³ It is better not to use a thread, but to separate from it one of the elementary fibers of which it is composed.

water. A few drops of the watery solution are evaporated with nitric acid to dryness, and the residue exposed to the fumes of ammonia. The characteristic purple color of the murexid test is produced (p. 673). Another portion of the aqueous solution is evaporated to a thin syrup, and a few drops of hydrochloric acid added. The characteristic uric-acid crystals will be produced. Another portion is allowed to stand without the addition of acid. At the bottom and on the walls of the vessel will be deposited crystals of sodium urate. Garrod found that in non-gouty subjects the crystals of uric acid were but rarely produced by this method. Garrod made quantitative estimations and found the amount of uric acid in the blood to vary between 0.003 and 0.0175 per cent.

Von Jaksch¹ gives the following procedure for the determination of the amount of uric acid in the blood: 100 to 300 cc. of blood are diluted with three or four times its volume of water. The mixture is heated on the water-bath, and when coagulation commences, a few drops of acetic acid (S. G. 1.0335) are added until the mixture is faintly acid. The fluid is allowed to remain at boiling temperature for fifteen minutes, filtered, and the residue washed with hot water. If the filtrate be not perfectly clear, a small amount of sodium chlorid may be added, and the filtrate heated again with acetic acid on the water-bath and refiltered. After cooling sodium phosphate is added to prevent the precipitation of uric acid, and the amount of uric acid in the mixture estimated by the Salkowski-Ludwig method. The filtrate obtained by this method is, after the addition of HCl, evaporated to 10 cc., and allowed to stand for twenty-four hours (p. 638). Crystals of uric acid are precipitated and collected on a weighed asbestos filter, washed with water and with alcohol, and weighed. They should show the characteristic form on microscopic examination. They may also be tested qualitatively by the murexid test. In case no crystalline precipitate is obtained, the solution may be evaporated to dryness and tested by the murexid test.

Von Jaksch was able to detect uric acid in the blood after it had been freed from albumin by Hopkins' method. (See p. 639.) The method may be carried out by adding to the filtrate from the coagulated albumin 20 grams of ammonium chlorid, and allowing the mixture to stand in a cool place for twenty-four hours. The uric acid is precipitated as sodium urate and may be identified by the murexid test.

Kowarski's method for uric-acid determinations may be similarly employed. (See p. 639.)

Von Jaksch found that the blood under normal conditions did not contain notable quantities of uric acid, but large quantities—up to 0.008 gm. in 100 cc. of blood—were found in pneumonia, affections of the kidneys, in diseases associated with dyspnea, especially heart affections and pleurisy. This is not the case in acute rheumatic arthritis and typhoid. In spite of the fact that an increased amount of uric acid is not pathognomonic for gout, it appears to the author that the differentiation of gouty affections of the joints from those of rheumatic origin by means of the determination of uric acid in the blood is of considerable diagnostic importance, especially if the quantitative estimation give results within the values given on p. 856. In fact the demonstration of increased amounts of uric acid in the blood is frequently the only means of differentiating gouty joint affections from those which are not.

THE OXIDASE REACTION OF THE BLOOD

The neutrophile leukocytes, but not the lymphocytes, contain an oxidizing ferment which changes the color of guaiacum resin solutions without the addition of hydrogen dioxid or oil of turpentine.² This property of the leukocytes can be shown in the blood itself, most easily in myelogenous leukemia. According to Nägeli, the reaction is carried out by dissolving a few drops of blood in 2 to 4 cc. of distilled water, thus setting free the oxidizing ferment. The blood solution is then overlaid with a solution of gum guaiacum in alcohol (p. 574, note 1). After a time the ring of contact becomes green to blue. The color is not, however, permanent. If the test be negative, the blood solution, before the addition of the guaiacum solution, may be allowed to stand

¹ Zeit. f. Heilk., 1890, xi, 415; Fodor, Centralbl. f. klin. Med., 1895, xvi, 865.

² E. Meyer, Münch. med. Woch., 1903, No. 35.

for twenty-four hours in order to set free more of the ferment and then overlaid with the resin solution. The reaction cannot be confused with the ordinary hemoglobin reaction, for with this test either oil of turpentine or hydrogen dioxid is necessary. According to Nägeli, this reaction is positive in cases besides those of myelogenous leukemia when the leukocyte count is above 20,000. According to this investigator, only the older neutrophile cells give the reaction, for he found in an acute case of myeloid leukemia that the reaction was negative, owing to the predominance of myeloblasts.

In making the test it is necessary to make a control to be certain that the guaiacum solution does not become blue from contact with water alone. This takes place with certain samples of the gum, and also when ordinary tap-water containing traces of iron is used instead of distilled water. Instead of the gum one may use a colorless alkaline solution of phenolphthalin (not phenolphthalein). This changes in the presence of an oxidizing ferment into phenolphthalein, which gives a red color with alkalis.

TESTS FOR BILIARY PIGMENTS IN THE BLOOD

The investigation of the blood-serum for biliary pigments has often afforded the author valuable information where it was necessary to determine the presence of an affection of the liver in the absence of jaundice, or where the discoloration of the patient's skin was doubtful. This method seems to be particularly important in the diagnosis of difficult cases of cholelithiasis or cirrhosis of the liver. In these cases bile-pigments may be found in the blood where the urine yields a negative test. In order to test for bile-pigment one or more cubic centimeters of blood are withdrawn from a vein with a Pravaz syringe, the blood is allowed to coagulate in a test-tube, and to stand until a sufficient amount of serum is expressed from the clot. Serum containing bile-pigments is usually to be distinguished by its marked yellowish or greenish color. The foam produced on shaking is distinctly yellow. If sterile serum be allowed to stand at body temperature for some hours, it gradually assumes a greenish color (von Jaksch). Gmelin's reaction (see p. 575) gives a positive test. The coagulum produced by the nitric acid is greenish in color. Warming the serum for fifteen minutes to 60° C. may also produce a green color. Normal serum does not give this reaction. More information is needed to decide whether, under certain conditions, the lipochrome and lutein of the blood may not give similar reactions. Regarding the morphologic characters of blood in jaundice and the resistance of the red cells see pp. 844 and 770.

EXAMINATION OF THE BLOOD-SERUM FOR UROBILIN¹

A definite volume of serum is shaken with chloroform. An emulsion is formed which may be separated either by centrifuging or in the following way. Into the neck of a funnel is introduced a piece of absorbent cotton large enough to absorb the larger part of the emulsion. The emulsion is poured on the cotton, which is pressed down with a glass rod. The liquid will then flow into a test-tube placed underneath the funnel in two separate layers. The chloroform solution is then removed with a pipet, and an alcoholic solution of zinc acetate (0.1 per cent.) is added until no more turbidity takes place. If urobilin be present, a distinct green fluorescence will appear.

DIAGNOSIS BY AGGLUTINATION TESTS. GRUBER-WIDAL SERUM-TEST IN TYPHOID FEVER, AND OTHER ATTEMPTS TO MAKE USE OF AGGLUTINATION IN DIAGNOSIS

The Gruber-Widal test is based upon the fact that the blood-serum of patients who are convalescing from typhoid, or of animals immunized to typhoid, according to the investigations of Gruber, Durham, and Pfeiffer, influences the typhoid bacilli

¹ According to Guiart and Grimbart, *Précis de diagnostique chimique*, etc., Paris, Rudeval, 1906.

in a test-tube in such a way that the latter lose their motility and form clumps which may be recognized microscopically. A similar phenomenon is observed when cholera-immune sera are added to cultures of cholera bacilli. This phenomenon has been attributed to the presence of peculiar hypothetic substances in the immunized serum, which have been called agglutinin or glabrificin by Gruber, and paralyisin by Pfeiffer.¹ These substances are not identical with the bactericidal nor immunizing substances of immune serum.

Based upon this observation, Widal² devised a peculiar diagnostic method for recognizing typhoid, for he noticed that this peculiarity is shown not only by the serum of convalescents, but also by the serum taken during the disease, and even quite early in the attack. He proposed two methods for testing the serum-reaction of the questionable typhoid cases—the so-called microscopic and macroscopic methods. To prevent evaporation, a few drops of freshly drawn blood are put into a closed tube of narrow caliber. The small vials in which homeopaths dispense their sugar pills may be used, or the blood may be drawn into Wright tubes, which are afterward sealed in a flame and in which it may be preserved for several days. After coagulation the serum expressed from the clot or that obtained by centrifuging is pipeted off. The serum which separates by spontaneous coagulation is employed. In the beginning Widal demonstrated the reaction microscopically by simply adding a drop of the serum to a drop of typhoid broth culture, of not more than twelve to twenty-four hours' growth, upon a slide. Under the microscope the bacilli in the broth culture must show very active movement. If the reaction be positive, the bacilli will cease to move within from a few minutes to half an hour and become clumped, while the intervening fluid will be free from bacilli. The second method depends upon the macroscopic appearance of a typhoid broth culture to which the serum of the patient in question has been added. The control culture is evenly clouded, but a culture to which a moderate amount of typhoid serum has been added will clear up, on account of the agglutinated bacilli settling to the bottom of the tube.

It has, however, been demonstrated in the Bern Clinic that this macroscopic serum reaction is not nearly so reliable as the microscopic test.

To obtain reliable results, the microscopic reaction had to be modified, since it was found necessary to take into account the dilution of the serum, for it was soon discovered that in low dilutions the serum of some people not suffering from typhoid had a moderate power of agglutinating typhoid cultures. It was therefore found necessary to determine that a certain very small quantity of the serum

¹ Van Calcar (*Dialyse, Eiweisschemie und Immunität*, Leipzig, A. Barth, 1908) has recently, as a result of a noteworthy series of studies, elaborated a really illuminating theory of agglutination, satisfactory both from a chemical and a biologic point of view. This theory attributes agglutination to a specific precipitin reaction, as Paltauf had already assumed. The formation of a precipitate through the combined action of the typhoid serum and the typhoid culture effects the phenomenon of clumping as a side issue, due to mechanical causes. Paltauf, in accord with the current theory of specific precipitins, assumes a precipitation of a specific constituent of the bacteria by its antibodies; van Calcar concludes that the substance precipitated is a globulin from the serum itself. The globulin precipitate, according to van Calcar, is due to the specific digestive ferments of the immune serum, which are called forth by the specific protein serving as the antigen. Consequently if the antigen-protein and the immune serum be brought together, the former is decomposed. The amino-acids resulting from this decomposition cause a precipitate of globulin, which is extremely sensitive to acids. In this reaction the globulin plays, as it were, merely the part of an indicator. According to this theory, the specificity of the reaction depends not upon a specific precipitin, but merely on the presence of that specific immune serum which decomposes the particular antigen, and thereby causes the precipitation of the globulin. Thus the agglutination reaction is identical with the specific precipitin reaction of the serum in infectious diseases first noted by Kraus. It is, however, much more easily detected, because a minimum, otherwise inappreciable, precipitate is rendered visible by the clumping of the bacteria.

² See Widal, *Semaine médicale*, 1896, No. 33, p. 259, and the numerous confirmatory results published in this journal of the same year. Also the contributions of German authors, in particular those of Stene, *Centralbl. f. inn. Med.*, 1896, No. 49, and Breuer-Lichtheim, *Berlin. klin. Woch.*, 1896, Nos. 47 and 48. Finally, Widal's chief work on the subject, M. F. Widal and M. A. Sicard, *Annales de l'Institut Pasteur*, 1897, vol. xi, No. 5.

would exert this action in order to consider the test positive for the diagnosis of typhoid.

Widal's reaction is performed quantitatively in the Bern Clinic as follows—a convenient and reliable method:¹ A barely turbid dilution of an actively motile twelve- to fifteen-hour agar culture of typhoid bacilli in sterile physiologic salt solution is used. This dilution is obtained by pouring the salt solution directly into the agar tube, shaking, and, if necessary, rubbing off a bit of the growth with a sterile platinum loop. If the mixture be too turbid, it may be partially cleared by filtration or centrifuging.

Two series of small glass dishes, A, B, C, D, and I, II, III, IV, V, are set out. (See Fig. 317.) The former are used in diluting the serum, which is performed as follows:

By means of a dropper, best made by drawing out a glass tube, one drop of the serum to be tested is placed in each of dishes A, B, and I. The dropper is then washed, and in A are placed 4, in B 9, drops of physiologic salt solution. This is mixed with the serum by means of a platinum loop. Thus we obtain in A a dilution of 1 : 5, in B one of 1 : 10. To make dilutions of 1 : 50 and 1 : 100 one drop of the mixture in B is mixed in C and in D with 4 and 9 drops respectively of physiologic salt solution. Thus in C there is a dilution of 1 : 50, in D one of 1 : 100. Higher dilutions may be made if desired in the same manner.

One drop each of dilutions A, B, C, and D is now placed in dishes II, III, IV, and V respectively. Between each transfer the pipet must be rinsed in water. In each of dishes I, II, III, IV, and V are then placed 9 drops of the suspension of bacilli, always using the same pipet, and a careful mixture is made by means of the sterile platinum loop, which is then immediately flamed. The addition of the emul-

Fig. 317.—Manner of diluting the serum and arrangement of the dishes in the Gruber-Widal reaction.

sion of bacilli makes the dilutions ten times as high throughout, so that the final dilutions are I = 1 in 10, II = 1 in 50, III = 1 in 100, IV = 1 in 500, V = 1 in 1000. All the dishes contain the same amounts of serum dilution and bacteria.

From each dilution a fresh microscopic preparation is made by covering a drop placed on a slide with a cover-slip, under one edge of which a second cover-slip is placed. This insures a wedge-shaped layer of fluid of sufficient thickness and very convenient for examination. A little vaselin is smeared around the edges of the cover-slip in order to prevent evaporation, and the slide is kept at a temperature of 37° to 40° C.² Every half-hour they are examined for agglutination with a No. 7

¹ See M. von Wyss, *Klinische Untersuchung über Erscheinungen von Agglutinationshemmung bei der Anstellung der Gruber-Widalschen Reaction*, Inaug. Academ. Dissert., Bern, 1906.

² The assertion that the agglutinating power of the serum is strongest at a temperature of 50° to 55° C. has not been confirmed by recent studies. The question of the optimum temperature for the Widal reaction is much complicated by the presence in the serum of substances which hinder agglutination (p. 860); for it is quite conceivable that in case the influences favoring and those hindering agglutination be differently affected by temperature according to the proportions of the agglutinin and the substances hindering agglutination, the end-result may be influenced by the temperature in an apparently irregular way. Not only should all possible dilutions of the serum be examined, but these should be placed in different temperatures if one wish to be sure not to overlook any possible agglutination. One may conform to the condition "in different temperatures" if one use the remainder of the dilutions in the method described above for examination at ordinary temperatures. Many negative Widal's may be explained by the complicated influence of dilution and temperature.

objective (Zeiss). All the apparatus, as well as the remaining culture, should be disinfected in bichlorid solution after use.

[A somewhat simpler and more convenient method than the above is as follows: Collect about 10 drops of blood in a small sterile test-tube and allow it to clot. Mix 1 loopful of the serum with 4 loopfuls of physiologic salt solution previously placed on a clean glass slide. This is dilution No. 1 (1 in 5). Mix 1 loopful of dilution No. 1 with 4 loopfuls of salt solution on a second slide. This is dilution No. 2 (1 in 25). Mix 1 loopful of dilution No. 2 with 1 loopful of salt solution on a third slide. This is dilution No. 3 (1 in 50). Now transfer 1 loopful of each of these dilutions to each of three clean cover-slips and add 1 loopful of a twelve-to eighteen-hour broth culture of *Bacillus typhosus*. The final dilutions are thus 1 in 10, 1 in 50, and 1 in 100. Finally, mix 1 loopful of the culture with 1 loopful of salt solution on a fourth cover-slip. This is the control. A hollow-ground glass slide rimmed with vaselin is then inverted upon each cover-slip, then turned right side up, and the hanging drop examined under the microscope. The capillary tubes employed by Wright in opsonic determinations may be employed to collect the blood, and, to one accustomed to their use, are more convenient and time saving.—Ed.]

In pronounced cases of typhoid the agglutinating action of the serum may be so marked that even with a dilution of 1 : 100 the typhoid bacilli will lose their power of motion and will adhere in clumps immediately after the addition of the serum. When the agglutination is less vigorous, the reaction may not be manifest for a considerable time, or it may occur only in the more concentrated dilutions. Before an absolute diagnosis of typhoid fever is made from the serum action alone, agglutination should take place within an hour with a dilution of the serum of 1 : 50. The sooner clumping occurs, the safer one is in expressing an opinion. The reaction should, however, be called positive for typhoid, even if (using a dilution of 1 : 50) complete agglutination occur in one to two hours.

Different typhoid cultures vary in their susceptibility to clumping, so that each observer should make himself familiar with the peculiarities of his own cultures. This explains many variable results reported.

In some cases of typhoid fever the reaction may be positive as early as the first week, but in most cases it may not be expected until the second or even the third week of the disease. Not uncommonly, however, the reaction is first positive in the fourth week or even during convalescence. In such cases its practical value is, of course, somewhat questionable. This is true even if one take into account the cessation of motility mentioned below, and is not misled thereby. The same statements apply to the disappearance of the reaction. This may occur a few weeks after the recession of the fever, but usually not for four to five months. Cases in which a positive Widal reaction can be obtained several years after recovery are rare, but to avoid mistakes it is important to remember that they do exist.

The supplementary demonstration of a positive reaction in the mildest or quite latent, unrecognized cases of typhoid (bacillus carriers) is of significance in explaining epidemics. By its aid the cause of the continuance of an epidemic and the common source of apparently isolated cases connected only by such a bacillus carrier may be established.¹

The frequently observed positive Widal reaction in *icterus* is noteworthy. Since it is not constant, we cannot assume that it is caused by the bile in the blood. Direct experiment supports this statement. It may be that it occurs in cases of jaundice which are caused by bacteria related to typhoid bacilli, *i. e.*, belonging to the same group.

In this connection the author will record what he believes to be a new observation (first described by Grünbaum), made independently in his clinic during an epidemic of typhoid fever. Early in the disease the serum of the patients produces more marked agglutination in weaker than in stronger concentrations: but this condition is reversed during the course of the disease. This indicates that, in addition to the agglutinative effect of the serum, there is a counteraction against agglutination early in the disease, which may be overcome by the more marked dilutions. Ehrlich's school considers this due to the influence of an agglutinoid, *i. e.*, a substance resembling agglutinin in having a common origin and possessing the same "haptophore" group as it, and therefore possessing the same affinity for the typhoid bacilli, but which does not agglutinate because the "zymophore" group is different. If one assume that there is less agglutinoid in typhoid serum, but that it is more active than the agglutinin, one can understand how agglutination seems to be

¹See Nägeli, Ueber die Typhus epidemie in Oberbipp, Correspondenzbl. f. Schweiz. Aerzte, 1899, No. 18.

arrested, because the agglutinoid, on account of its greater activity, combines with the protein of the bacilli, while this does not occur in less concentrated mixtures because of the dilution. This, of course, is directly opposed to van Calcar's theory of agglutination (p. 858, note 1). Further investigations must be undertaken in order to determine whether these differences between the effects of concentrated and dilute serum mixtures are of any value in predicting the clinical course of a case. So far as our experience goes at present this seems not to be the case. At all events, the observation is of practical importance, since it demonstrates that a negative result should never be assumed simply because agglutination is not obtained by a concentrated serum, but that an opinion should be withheld until the test has been made with a much diluted serum, for it has not yet been shown whether far higher dilutions than those usually employed have not certain advantages, or whether the influences inhibiting agglutination do not preponderate in the usual dilutions, and whether, therefore, many negative results may not be avoided by choosing still higher dilutions.

In order to have fresh typhoid cultures always on hand it is best to transfer the glycerin-agar cultures every eight or fourteen days, as otherwise the cultures will degenerate and die off. A fresh agar culture is prepared from the water of condensation of the agar culture twelve to fourteen hours before performing the test and placed in an incubator. Stock cultures, after being grown for a little while, are best preserved at the temperature of the room. Authentic typhoid cultures are best obtained from the spleen of a fresh typhoid corpse (with the ordinary precaution to avoid contamination, *i. e.*, singeing the surface).

Attempts have recently been made to substitute for the original Widal reaction analogous reactions with typhoid bacilli killed with formalin and preserved (Ficker's Diagnosticum¹).

On the other hand, de Rossi² has found that typhoid (bouillon) cultures killed by exposure to 58° to 60° C. for one hour, are even more sensitive than fresh cultures. They may be kept for three months.

Krauss's precipitin reaction, obtained by mixing extract of typhoid bacilli and typhoid serum, has been recommended as a substitute for the Widal reaction. It obviates the use of living typhoid cultures, but it is less delicate than the agglutinin reaction. (See p. 858, note 1.)

The Gruber-Widal test has recently served to cause considerable confusion through the creation of the pathologic conception of paratyphoid. This term is used to designate certain forms of typhoid fever in which the Gruber-Widal test is negative with ordinary typhoid bacilli, whereas a positive reaction is obtained if a so-called paratyphoid culture be used. The paratyphoid bacillus is an organism obtained originally in diseases resembling typhoid fever in man, and distinguished from *Bacillus typhosus* by certain slight and by no means pronounced cultural differences. Serum from patients with paratyphoid is claimed to agglutinate the paratyphoid bacillus, just as that from patients with true typhoid agglutinates typhoid bacilli. Paratyphoid fever is said not to differ clinically from true typhoid, though the disease is usually milder, nor does autopsy show any pronounced differences, except that the abdominal lesions are less severe. Bacteriologists lay great stress on the fact that the paratyphoid bacillus, in contrast to *Bacillus typhosus*, is markedly pathogenic for mice and guinea-pigs, and that even small subcutaneous doses cause septicemia and death. These reasons seem to the author to be insufficient to warrant the establishment of paratyphoid fever as an independent and specifically distinct disease. To him it appears doubtful if the two diseases can be certainly distinguished clinically or anatomically. Moreover, the bacteriologic characteristics themselves vary so that even among paratyphoid bacilli many varieties have been isolated.³ Further, the agglutination phenomena of the two so-called varieties permit of no sharp differentiation, since up to a certain degree, *i. e.*, within certain limits of dilution, the typhoid bacillus is agglutinated by paratyphoid serum, and vice versa, while the typhoid serum sometimes fails to agglutinate the *Bacillus typhosus*, and paratyphoid serum fails to clump the paratyphoid bacilli. These should be logically sufficient grounds for protesting against the attempt to class typhoid and paratyphoid as two essentially different maladies. The author

¹ Furnished with directions for use by Merck in Darmstadt. More recently a similarly made paratyphoid "diagnosticum" has been prepared. In regard to the importance of the diagnosis of paratyphoid see below.

² Centralbl. f. Bact., first part, vol. xl, pp. 426-430.

³ See Kolle, *Die experimentelle Bakteriologie der Infektionskrankheiten*, second ed., Wien, 1908, p. 222, et seq.

can hardly understand the ready acceptance of this distinction by certain clinicians. We know, from a thousand examples in the bacteriology and experimental pathology of infectious diseases, how markedly the characteristics of a bacterium may vary under different nutritional conditions in artificial culture-media, as well as in the body, how not merely the morphology, but also the virulence and the chemical properties of a particular species, can be changed because of its adaptation to certain conditions of life. Typhoid and paratyphoid bacilli then are apparently only different varieties, not different species. The only satisfactory explanation of the variations is that they result from natural selection, because the typhoid bacillus can assume different characteristics depending on the varying susceptibility of the chemically different soil in the living body, and that these are retained, up to a certain degree, by succeeding generations without, as well as within, the infected organism. Characteristics resembling those of the paratyphoid bacillus, exhibited also by *Bacillus typhosus* as regards the peculiarities of agglutination, are not, therefore, in the author's opinion, intrinsic qualities of these germs, but are the products of natural selection in certain forms of the disease caused by the typhoid bacillus. This does not, of course, exclude the possibility that the bacilli generated in a given case of typhoid may retain their acquired characteristics to a certain degree in a number of subsequent generations. It should be remembered that individual epidemics of other infectious diseases, such as scarlet fever and measles, quite frequently present points of difference, though up to the present no one has subdivided them into new groups. It is true that an attempt at further subdivision has recently been made even here (the so-called "morbus tertius"), but it is hardly justifiable, because the transition forms are so apparent and because no bacteriologic data are available. An attempt to cross-breed paratyphoid and typhoid bacilli would be of interest. With just as much reason might we differentiate parapneumococci, paradiphtheria bacilli (as indeed has, in a sense, already been tried, the name pseudodiphtheria bacilli being used), parastaphylococci, parastreptococci, etc. Into what confusion would we thus be plunged and at what variance would such a tendency be with the aims of other departments of scientific botany! The author does not deny that the differences discovered between ordinary typhoid and paratyphoid bacilli possess a certain clinical interest, chiefly because a positive paratyphoid reaction enables one to recognize also those cases of typhoid which give a negative Widal reaction. He cannot, however, allow the right of bacteriology to introduce new diagnoses on the grounds of such indefinite and minute distinctions, thereby overstepping the boundary of an aid to clinical knowledge and attempting to rule the clinician.

In *tuberculosis* also an attempt has been made to obtain an agglutination of a homogeneous suspension of sterilized tubercle bacilli (to be obtained from the Höchst laboratories). This, however, has not proved to be of any practical value. The *agglutination test of Malta fever*, on the other hand, is useful. (See p. 813, et seq.)

EXAMINATION OF THE BACTERICIDAL POWER OF THE BLOOD

Hamburger¹ has shown that the bactericidal power of the serum depends in large measure upon its content of CO₂, because the degree of alkalinity also depends on this. In order, therefore, that the conditions of any test of the bactericidal power of the blood may correspond with those in the living body, the blood should be defibrinated, care being taken to prevent the introduction of any air. Hamburger accomplishes this by shaking the blood with glass beads in a closed vessel filled to the brim. As a matter of fact, this procedure is of no advantage, because large amounts of human blood can be obtained only by employing artificial venous stasis, as a result of which the CO₂ content is artificially increased by an unknown amount. It is, therefore, rather to be recommended that the blood be arterialized before the serum is expressed. This is most simply done by letting the blood flow in a thin stream along the side of the test-tube in which it is collected. One may then wait for spontaneous coagulation and draw off the serum expressed from the clot under aseptic precautions. Or one may defibrinate the blood by shaking it up with glass beads under aseptic precautions, avoiding the entrance of air, and may then centrifuge it or allow the red cells to settle. Hamburger places the serum so obtained in two sterile test-tubes, one of which is heated to 60° C. for ten minutes. Both tubes are then inoculated by means of a sterile capillary pipet with an equal amount of the particular bouillon culture to be tested. The amount of culture used must be so small that no appreciable turbidity results. The tubes

¹ Osmotischer Druck und Ionenlehre, 1902, vol. i, p. 282, et seq.

are then placed in the incubator, and the time at which the first sign of turbidity appears is noted. The difference in time between the appearance of turbidity in the two tubes is an approximate measure of the bactericidal or inhibitory action in the unheated serum. According to Hamburger, when turbidity has appeared in the tubes, equal amounts of the fluid may be placed in narrow tubes (Fig. 305, p. 767), centrifuged, and the height of the sediment measured. It is well, however, in either case to make sure, by microscopic examination of dried smears, that the turbidity depends essentially on the bacteria and not on an amorphous protein precipitate, for in the latter case the method is unreliable. Hamburger recommends both methods, by means of which he studied the influence of CO₂ in the blood on the bactericidal power of the blood-serum. Very unreliable results had been obtained by him with the customary counting method by means of agar plates. The supposition that in this method the germs can be completely isolated from one another by mixing the serum with the melted agar is not warranted by facts.

THE WASSERMANN-NEISSER-BRUCK SERUM-REACTION IN SYPHILIS

In the diagnosis of doubtful cases of syphilis we must, in addition to the demonstration of the *Spirochæta pallida* (p. 815, et seq.), consider the so-called serum-reaction of Wassermann, Neisser, and Bruck. It is of considerable importance, from the point of view of therapy, not only in detecting cases of visceral syphilis, but also in determining the etiology of cases of tabes dorsalis and general paresis, because it is positive in a relatively high percentage of these cases.

This so-called serum reaction depends on the deviation of the complement, a method introduced by Bordet and Gengou. These writers have shown the existence of characteristic chemical affinities between the antigen and the corresponding amboceptor. It is by means of these affinities that the demonstration of the amboceptor by means of its corresponding antigen and vice versa is possible. We know that by injecting the blood-cells of any particular species of animal into an individual of another species we may obtain from the blood of the latter a sort of immune serum which contains a specific amboceptor or immune body against the cells used for the injection. The action of this amboceptor, *i. e.*, of the particular antiserum, is shown by its dissolving in vitro the kind of corpuscles used, in case the mixture contain at the same time the so-called complement—that puzzling substance present in every normal serum, and called the alexin by the French school. After a rabbit has been inoculated with sheep's blood, its serum contains a specific immune body, which in the test-tube dissolves sheep's corpuscles in the presence of the complement. If the rabbit serum be fresh, it contains the complement itself. Heating and aging of the serum destroy the complement, and it is, therefore, necessary, in order to re-establish the hemolytic action, to add the complement in the form of fresh serum from some animal or other, for instance, the fresh serum of a normal guinea-pig. Such a combination of blood-corpuscles, amboceptor, and complement is usually called a specific hemolytic mixture. According to Ehrlich, the hemolytic effect results from the fact that the amboceptor, serving to some extent as a linking body, anchors the complement to the red cells, thus enabling it to dissolve them. In such an experiment the red cells play the part of antigen to the hemolytic amboceptor, *i. e.*, the same part as that played by the bacteria to their specific antibodies in bacteriolytic experiments. The complement is essential to the success of the experiment, and it follows from this that a mixture of blood-corpuscles and the particular specific hemolytic amboceptor may be utilized as an indicator of the presence of the complement. If free complement be present, hemolysis occurs; if it be lacking, there is no hemolysis. If now there be added to the hemolytic mixture some other "foreign" amboceptor and its corresponding antigen, we have present in the mixture two amboceptors with their corresponding antigens beside the complement. There then begins a kind of contest between the two amboceptor-antigen groups for the complement, and if certain mass relations obtain, the complement will be so far deviated to the "foreign" amboceptor which has been added to the hemolytic mixture, *i. e.*, anchored to the corresponding antigen, that (in the presence of the proper proportions) the complement requisite for hemolysis is lacking and, therefore, the hemolysis itself either fails or is at least retarded. The test is still more accurate if the "foreign" amboceptor, its antigen, and the complement be first mixed together, allowed to stand a while, and, then, after union of these three substances, the blood-corpuscles with their specific hemolytic amboceptor be added. The result of this Bordet-Gengou test is called arrest of hemolysis by deviation of the complement.

By means of this procedure the etiologic significance of certain bacteria in infectious diseases, *e. g.*, that of Bordet's bacillus in whooping-cough (p. 720) and Kruse's

bacillus in dysentery (p. 530, et seq.), may be shown. Wassermann uses it as an aid in diagnosis to demonstrate either syphilitic antigen (the poison of syphilis) or syphilitic antibodies, both of which may be present in syphilitic organisms. Usually the practical diagnosis of syphilis depends on the demonstration of syphilitic antibodies. One must have at hand for this demonstration the ingredients needed in an ordinary test for specific hemolysis, *e. g.*, sheep's red cells, amboceptor from rabbits immunized against these, and fresh guinea-pig serum containing the complement, beside the syphilitic antigen, *e. g.*, an extract of the liver of a syphilitic fetus. With these is sought the syphilitic amboceptor or immune body, which may be present in the blood-serum and even in the cerebrospinal and other body fluids of the person examined. The rabbit serum containing sheep amboceptors and the human serum to be examined must be deactivated, *i. e.*, freed from complement. The object of this is to use a same amount of complement in all the tests in spite of the different additional amounts of hemolytic amboceptor and of the serum to be tested. The technic of the Wassermann-Bruck-Neisser test (omitting the complete details of the procedure to be given later) is as follows: For a few weeks a rabbit is injected at definite intervals with a definite amount of sheep's red cells, and the serum obtained from it is deactivated by heating to 56° C. for a definite time. Rabbit serum so treated contains the hemolytic amboceptor. Fresh guinea-pig serum is also procured. Syphilitic amboceptor in the form of an extract of the liver of a syphilitic fetus is now mixed in a test-tube with the human serum to be tested and with complement in the form of fresh normal guinea-pig serum, to which are added sheep's blood-cells and the corresponding amboceptor. The exact proportions of the ingredients used are given below. The entire mixture is then kept at 37° C. for one or two hours. If the serum tested contains syphilitic amboceptor, hemolysis either fails entirely or is much delayed, because the complement necessary for hemolysis is taken up.

The following are the detailed directions worked out in Neisser's clinic and formulated by Tage (Münch. med. Woch., 1908, No. 23).

1. *Obtaining the Substances Necessary for Reaction.*—The syphilitic antigen is obtained by finely dividing the liver of a syphilitic fetus, adding ten times its volume of absolute alcohol, shaking it up with powdered glass in a shaking apparatus for twenty-four hours, and filtering.

2. *Obtaining the Sheep's Blood-corpuscles.*—Fresh sheep's blood is defibrinated at the slaughter-house by shaking it up with steel shavings. Blood so defibrinated may be preserved for several days in the ice-box. For use, the necessary amount is washed twice with a double quantity of salt solution in the centrifuge and the water used for washing is pipetted off, so that there remains a pulpy mass of corpuscles mixed with a little salt solution.

3. *Obtaining the Amboceptor for the Red Cells.*—Into the ear vein of a large rabbit $\frac{1}{2}$ cc. of the sheep corpuscle suspension is slowly injected. This is repeated four times at intervals of one week, and after five weeks have elapsed the animal is bled to death from the carotid. In order to obtain as much blood as possible the animal's abdomen is compressed during the hemorrhage. The blood is allowed to stand in vessels stoppered with cotton-wool for two hours, when the blood-clot is separated from the sides of the vessel with a platinum wire, and after twelve hours the serum is poured off. This is deactivated by heating in the water-bath to 56° C. for a half-hour; it is dried *in vacuo* at a temperature of 40° C., and portions of 0.3 gm. each of the residue are transferred to brown glass tubes in which it is kept for future use. For use 0.3 gm. of the dried residue is dissolved in 3 cc. of distilled water.

4. *Obtaining the Complement.*—A guinea-pig which has fasted for a day in order to assure bacteria-free serum is bled, and the fresh serum with complement contained in it is obtained in the same way as the amboceptor from the rabbit. This must be freshly prepared for each test.

5. *Obtaining the Fluid to be Examined.*—About 20 cc. of blood is withdrawn from a vein of the patient to be examined (p. 731), allowed to clot, and the serum obtained as in 3 and 4. If the cerebrospinal fluid is to be used, it is withdrawn by lumbar puncture in the usual way (p. 937 et seq.). The serum as well as the cerebrospinal fluid is deactivated by heating to 56° C. for half an hour, thereby freeing it of complement, and preserved in the cold.

The complexity of the process for obtaining the substances necessary for the reaction, especially the syphilitic antigen and the blood-cell amboceptor, makes it desirable that these might be dispensed from some central station.

The Actual Technic of the Reaction.—The substances entering into consideration are always used in dilutions for which 0.85 per cent. salt solution is employed. For use, 1 cc. of the alcoholic extract of antigen is mixed with 3 cc. of salt solution; 1 cc.

of deactivated serum is mixed with 4 cc. of salt solution; 1 cc. guinea-pig serum is mixed with 9 cc. salt solution; 1 cc. of the amboceptor powder solution (0.3 in 3 cc. distilled water, see above) with 60 cc. salt solution; and finally 1 cc. sheep's blood-corpuscles "broth" with 19 cc. salt solution. These dilutions are always meant in the following directions concerning quantities of the amboceptor, complement, etc., used in the tests.

Preliminary Examination of the Individual Ingredients.—One cc. of the dilution of sheep's blood-cells, mentioned above, when mixed with 4 cc. salt solution, should show no trace of hemolysis on fifteen minutes' standing at incubator temperature; 1 cc. of the dilution of sheep's cells + 1 cc. of the dilution of complement + 1 cc. amboceptor dilution must give a clear solution in fifteen minutes at 37° C.; 1 cc. of the dilution of sheep's blood-cells + 1 cc. complement dilution + $\frac{1}{2}$ cc. amboceptor dilution should cause solution in half an hour; 1 cc. sheep's blood-cells + 1 cc. complement dilution + $\frac{1}{2}$ to $\frac{1}{4}$ cc. amboceptor dilution, in thirty to forty minutes; and the same quantity of the first two substances with $\frac{1}{2}$ to $\frac{1}{4}$ cc. amboceptor dilution in two hours. Should hemolysis occur too quickly in this preliminary test, the amboceptor dilution must be further diluted with an equal volume of salt solution. If it occur too slowly, the amboceptor powder solution must, on the contrary, be made stronger, 0.2 cc. instead of 0.1 cc. of the amboceptor powder solution being used in 60 cc. salt solution. In this preliminary test the mixture must always be brought up to 3 cc. by the addition of salt solution in order that the results may be compared.

It must further be determined as a control of the diagnostic test whether or not the antigen of itself alone (without antibody) or the antibody (serum) alone (without antigen) arrests hemolysis, for this sometimes happens. To this end two tests are to be made:

1. Two cc. antigen dilution + 1 cc. sheep's blood-cell amboceptor dilution + 1 cc. sheep's cells diluted + 1 cc. complement.

2. Two cc. of the serum to be tested + 1 cc. of dilution of blood-cell amboceptor + 1 cc. dilution of sheep's cells + 1 cc. complement. In both these tests uniform hemolysis must occur; if not, the antigen of itself or the antibody of itself (serum) has an influence in arresting the solution.

The Examination Proper.—This includes the following separate tests,¹ eight in number:

Test-tube 1 contains 1 cc. sheep's blood + 4 cc. physiologic salt solution.

Test-tube 2 contains 1 cc. complement + 1 cc. sheep's blood + 1 cc. amboceptor + 2 cc. salt solution.

Test-tube 3 contains 1 cc. normal serum + 1 cc. antigen + 1 cc. complement + 1 cc. sheep's blood + 1 cc. amboceptor.

Test-tube 4 contains 1 cc. syphilitic serum (for comparison) + 1 cc. antigen + 1 cc. complement + 1 cc. sheep's blood + 1 cc. amboceptor.

Test-tube 5 contains no serum + 2 cc. antigen + 2 cc. complement + 1 cc. sheep's blood + 1 cc. amboceptor. (This test has already been mentioned as a preliminary test.)

Test-tube 6 contains 1 cc. of the serum to be examined + 1 cc. antigen + 1 cc. complement + 1 cc. sheep's blood + 1 cc. amboceptor.

Test-tube 7 contains $\frac{1}{2}$ cc. of the serum to be examined + $\frac{1}{2}$ cc. antigen + 1 cc. complement + 1 cc. of sheep's blood + 1 cc. amboceptor + 1 cc. salt solution.

Test-tube 8 contains 2 cc. of the serum to be examined + no antigen + 1 cc. complement + 1 cc. sheep's blood + 1 cc. amboceptor. (This test also has been described as preliminary trial.)

Bruck recommends that in tests 3 to 8 the mixture containing the first 3 ingredients be kept in the incubator for one hour in order that the complement may be fully bound before the sheep's blood and the amboceptor are added. He likewise advises that the mixture of sheep's blood and the amboceptor be kept warm for one hour by itself. Not until then should all be mixed together.

The result of the different tests may be read after the tubes have been in the incubator for one hour. For a positive diagnosis of syphilitic antibodies in the serum tested, hemolysis must be absolutely lacking in tests 6 and 7, in which the serum tested and the antigen are present; and in tests 4 (containing serum known to be syphilitic) and 1, whereas in tests 2, 3, and 5 hemolysis must occur. Comparison with the test containing known syphilitic serum can be made to decide the question of a doubtful reaction (slight hemolysis).

¹ The author would again emphasize that the quantities refer to the dilutions mentioned above. Sheep's blood always means the given dilution of sheep's blood-cell "broth," etc.

Contrary to the whole basic idea of the method and to the nomenclature of the active substance contained in syphilitic serum (which has been retained above for better understanding), the Wassermann-Neisser-Bruck reaction has not proved itself to be strictly specific, *i. e.*, is not a specific test of the syphilitic antibody. For it seems that extract of guinea-pig's heart may be used with almost the same results as syphilitic antigen. Although this necessarily gives rise to grave doubts in the judicial mind of the critical observer as to the diagnostic significance of the reaction, nevertheless the reaction has made good and become established on purely empirical grounds. The few cases in which a positive reaction is obtained in spite of the fact that syphilis is absolutely excluded (scarlet fever) are practically of no moment, since the reaction soon becomes negative after recovery. Many workers actually use extract of guinea-pig's heart instead of syphilitic antigen, because the latter is so difficult to obtain. In consideration of this most striking fact the proposition has been made, and very properly, to represent this serum reaction in syphilis not as "specific," but merely as "characteristic" of the disease.

The varied modifications of Wassermann's technic chiefly concern the preparation of antigen. Marie and Levaditi¹ mash the liver of a congenitally syphilitic fetus in vacuo, pulverize it, extract in physiologic salt solution, centrifugalize, and use the supernatant fluid. Morgenroth and Sterz² preserve the syphilitic liver in the frozen state and use a small piece of it for each test. This bit is mashed in sea-sand, extracted in salt solution, filtered, and the filtrate used. Porgos and Meier³ extract in alcohol, filter, evaporate the filtrate in a vacuum below 40° C., and use a 1 per cent. solution of the resulting sticky mass. Landsteiner, Müller, and Pötzl⁴ make use of an extract of guinea-pig's heart or liver. Michaelis and Lesser⁵ shake and extract minced normal or syphilitic liver or normal heart with alcohol and use 1 part of the clear supernatant fluid in 4 parts of physiologic salt solution. Sachs and Rondoni⁶ use the following artificial antigen:

Sodium oleate (Kahlbaum).....	2.5	or	1.0;
Lecithin (Ovo, Merck).....	2.5	or	1.0;
Oleic acid (Kahlbaum).....	0.75	or	1.5;
Distilled water.....	12.5	or	5.0;
Alcohol.....	ad. 1000.0	or	1000.0.

One part of the above is diluted with 5 parts of physiologic salt solution.

Schürmann prepares the following:

Lecithin 0.3 in 50 cc. absolute alcohol;
Sodium glycerophosphate.. 0.3 in 5 cc. physiologic salt solution.

Thirty cc. of the above are mixed with 5 cc. lactic acid and 10 cc. of a 1 per cent. solution of ammonium vanadate.

NOGUCHI'S MODIFICATION OF THE WASSERMANN REACTION

Noguchi has considerably simplified the Wassermann reaction by using for reagents separate slips of filter-paper impregnated with complement, antigen, and amboceptor respectively, dried and standardized. His technic is as follows:

Reagents.—1. *Antihuman hemolytic amboceptor* is prepared in rabbits by injecting five or six times into the peritoneal cavity increasing doses (up to 20 cc.) of thoroughly washed human blood-cells at five or six days intervals. The blood of the rabbit is collected nine or ten days after the last injection and the serum allowed to separate. Either this serum or slips of filter-paper impregnated with it, dried and standardized, may be used.

2. *Complement* is fresh guinea-pig's serum, or slips of paper impregnated with the same, dried quickly at low temperature, and standardized.

3. *Antigen* is the acetone-insoluble lipoids of the organs; 1 part of the mashed tissue (liver, heart, or kidney of man, ox, dog, guinea-pig, or rabbit) is extracted with 10 parts of absolute alcohol for several days at 37° C., filtered through paper, and dried at a temperature below 40° C. by means of an electric-fan. The resulting

⁵ Berlin. klin. Woch., 1908, vol. xlv, 301.

⁶ Ibid., vol. xlv.

residue is extracted with ether, which is then allowed to evaporate. The residue from this is taken up with a small amount of ether and fractionated with 10 volumes of acetone. For the test the adequate quantity of a 0.2 per cent. emulsion of the residue (acetone-insoluble) after evaporation of the acetone in physiologic salt solution is used, or slips of filter-paper impregnated with an ethereal solution of the material may be employed.

4. *The suspension of human blood-corpuscles* is prepared by allowing 2 drops of blood from a normal individual to fall into 8 cc. of physiologic salt solution and then removing the fibrin by washing the corpuscles or by beating the suspension with a stick. It is more accurate to use a 1 per cent. suspension of the washed corpuscles, which is prepared by mixing the washed corpuscles from 1 volume of blood with 99 volumes of physiologic salt solution (but not 1 volume of the sedimented corpuscle mass to 99 volumes of saline).

5. *Serum to be Tested*.—About 1 or 2 cc. of blood from the patient are collected in a Wright tube. The clear serum which separates from the clot is used. No preliminary inactivation of the serum at 55° C. is required, unless the serum has been kept for several days after taking.

Six tests are made according to the following scheme:

	Test for diagnosis with the serum in question.	First control. Test with known syph- ilitic serum (positive reaction).	Second control. Test with normal serum (negative reaction).
Control tube without antigen for each test.	a. Patient's serum, 1 drop. ¹ (1) b. Human blood sus- pension, 1 cc. c. Complement, 2 units. ²	a'. Positive luetic se- rum, 1 drop. (3) b'. Human blood sus- pension, 1 cc. c'. Complement, 2 units.	a''. Normal serum, 1 drop. (5) b''. Human blood sus- pension, 1 cc. c''. Complement, 2 units.
Determinative tube containing antigen.	a. } b. } do. (2) c. } d. Antigen.	a'. } b'. } do. (4) c'. } d'. Antigen.	a''. } b''. } do. (6) c''. } d''. Antigen.

Incubate at 37° C. one hour.

Antihuman hemolytic amboceptor, 2 units³ to all tubes, 37° C. for two hours longer. Then at room temperature.

Reading the Reaction.—A negative reaction is shown by complete hemolysis in both tubes containing patient's serum irrespective of the presence of antigen. This usually occurs in one hour or less. A positive reaction is shown by complete absence or partial inhibition of hemolysis in the tube containing antigen, and complete hemolysis in the tube without antigen. Tubes 1, 3, 5, and 6, therefore, should all show complete hemolysis before the final reading of the reaction.

Results of the Noguchi Test.—In 1082 cases of syphilis, parasyphilis, hereditary syphilis, and suspected syphilis Noguchi's test was positive in 802, or 74 per cent. Of these, 39 had been under prolonged treatment for the disease and only 10.2 per cent. of them gave positive reactions. Noguchi's test is somewhat more frequently positive than Wassermann's reaction. Thus, in 244 cases of syphilis Noguchi's test was positive in 211 (86.4 per cent.), whereas Wassermann's reaction was positive in only 183 (75 per cent.). In 333 cases where syphilis could be excluded with a fair degree of certainty Noguchi's test was positive in 13 (3.9 per cent.). Treatment for syphilis has a marked influence in reducing the number and intensity of positive reactions. It is fair to say that a positive Noguchi reaction is strong presumptive evidence of syphilis and an absolute indication for specific treatment.

Dr. Noguchi has been kind enough to revise the above note and also the note upon his butyric acid reaction on p. 941. During the past eight months Dr. Noguchi has examined for me 105 specimens of blood carefully selected from my

¹ When working with inactivated serum (i. e., one from which complement has been removed by heating to 55° C.), 4 drops (0.08 cc.) should be employed.

² Either 0.1 cc. of a 40 per cent. solution of guinea-pig serum in salt solution or a slip of filter-paper containing 2 units of complement. A unit of complement is the smallest amount necessary to produce complete hemolysis with 1 unit of amboceptor.

³ A unit of amboceptor is the smallest amount necessary to produce complete hemolysis in a standard suspension of erythrocytes in the presence of an excess of complement (usually 0.02 cc. of guinea-pig's serum is taken as 1 complement unit).

services at the New York City and the French hospitals, and a few from other sources. In this series of cases were included many types of arteriosclerosis, nephritis, anemia, myocarditis, hepatitis, two cases of trichinosis, one of severe epidemic parotitis accompanied by severe stomatitis, and many other acute and chronic diseases.

In only one instance was there any question of a positive reaction when the results of treatment, the clinical diagnosis, the history of the subsequent course of the disease, did not prove its accuracy. Twenty of the cases which gave a negative reaction had almost certainly suffered from syphilis. Some of them had been under specific treatment to a slight extent shortly before the reaction was made. The others did not show any especial clinical improvement attributable to the institution of specific treatment. A careful study of these results has convinced me that a positive reaction, even though it be a weak one, is from the therapeutic standpoint a very important aid in diagnosis. If the blood exhibit a negative reaction, it should be tested again at a later interval. In 2 instances in this series of 20 negative cases the subsequent examination became positive.—ED.]

EXAMINATION OF THE MOUTH AND PHARYNX

Inspection is the most important method for examining the mouth and pharynx. For proper inspection the patient should open his mouth as wide as possible, and then move the tongue away from the place to be examined. The pharynx and soft palate are usually seen best if the base of the unprotruded tongue be depressed with a spatula or with the handle of a spoon, while the examiner steadies the patient's head at the same time with his other hand. Care must be taken not to apply the tongue-depressor too far back, for if the posterior portion of the base of the tongue or the pharynx be touched, gagging results and renders the examination difficult. The posterior wall of the pharynx can be seen better when the patient says "Ah!" and so elevates the soft palate. It is often very difficult, indeed, to examine the mouths of unruly children or of irrational patients. Sometimes closing the nostrils will make such patients open the mouth, while at other times we have forcibly to separate the jaws with a spoon, a depressor, or a mouth-gag. With unruly children, whether we employ the aid of a depressor or not, we should look quickly the moment the child opens his mouth to cry.

Palpation with the finger often assists in determining the condition of portions of the mouth which are situated farther back. Palpation of the nasopharynx or of the entrance to the esophagus to hunt for foreign bodies, retropharyngeal abscesses, or adenoids must be done very quickly, because it is extremely disagreeable to the patient and can be borne but a short time.¹ Unruly patients and children are apt to bite the examiner's finger unless the cheek is pressed in between the patient's teeth with the free hand. This is a better method than to employ appliances for protecting the fingers. The forefinger is better adapted for palpating adults, and the little finger for very young children. The introduced finger is hooked upward or downward, according to the region to be explored. The entire pharyngeal cavity can be palpated from the top of the larynx to the nasopharyngeal space above.

¹ [The application of a solution of cocain (2 to 4 per cent.) to the back of the pharynx will deaden the sensibility of the parts and allow a more careful digital examination.—ED.]

Such palpation must be carried out very quickly because of the discomfort occasioned by it and the danger of causing vomiting. The most important use of this procedure is the diagnosis of adenoid vegetations, and such other methods as posterior rhinoscopy (p. 905), or

Fig. 318.

Fig. 319.

Fig. 318.—Hutchinson's teeth in hereditary syphilis: Two upper middle incisors (second dentition) with deep transverse and longitudinal grooves; also concave edge of middle incisors. The length of the teeth is normal, but the width is diminished; hence, broad interspace in middle.

Fig. 319.—Upper middle incisors (second dentition) immediately after eruption; also four lower incisors. Lower surface of upper incisors is rough, due to prominent points of dentin. Upper teeth short and directed away from each other, forming a broad interspace. On the four lower teeth are numerous excrescences, due to deficient formation of enamel. Base of excrescences everywhere at same level.

Lindt's direct rhinopharyngoscopy, can serve only as partial substitutes for it in the examination of adults and of older children. To carry out such palpation the examiner should stand to the right of and

Fig. 320.—Hutchinson's teeth: The upper middle incisors (second dentition) and all four lower incisors are characteristic enough. The photograph was taken from a colored child, six years of age, who had been under Dr. McConnell's observation at the Vanderbilt Clinic for a year. She has saber shins, and when first brought to the clinic, presented a rash. An older sister has similar teeth. The mother has had two miscarriages since the birth of her last child. The original of this photograph has improved upon biniodid of mercury.

somewhat behind the patient, adults being seated in a chair, while children are best held in the lap of an assistant; he then steadies the patient's head by pressing it against his own chest, pushes the patient's cheeks between the teeth in the manner described above, in order to escape

being bitten, and rapidly introduces his index-finger, or in the case of children his little finger hooked upward, following closely the middle line of the mouth until the posterior pharyngeal wall is reached; the finger is then made to follow rapidly along the pharyngeal wall into the retropharyngeal space, first in the direction of the vomer and then toward the roof of the pharynx. He then rapidly palpates the posterior nares, the roof, and the lateral walls of the space, and especially the Eustachian prominences. To reach and properly palpate the left lateral wall of the rhinopharynx from the right side, the examiner must rapidly move over to the other side of the patient, at the same time slightly withdrawing his finger. If large adenoid growths be present, the whole retropharyngeal space is found to be filled with a soft mass, in consistence like a knot of earth-worms, which prevents palpating upward behind the uvula. If the adenoid growth be smaller, the retro-

Fig. 321. —All four upper incisors approach the type of Hutchinson's teeth. The lower incisors are practically normal. In this case the upper middle incisors are not characteristically peg-shaped, but the groove upon the cutting edge is a significant feature. No other facts relating to this case are known. It is probable that the teeth should be classified as Hutchinson's teeth.

pharyngeal space is found to be more or less patent, and a soft mass is felt only by flexing the palpating finger upward toward the roof. The finger is often blood stained by the examination, for the vegetations are usually very vascular and easily injured. Palpation of the adenoid growths often gives better results than posterior rhinoscopy, because the latter is not only difficult, but also shows the vegetations very much foreshortened. Palpation must, however, be carried out very carefully, as it may easily cause injury.

Lips.—The examiner should notice their color (pallor, cyanosis), the presence of aphthous ulcers, mucous patches, sordes, fissures (rhagades) or their scars, which leave diverging folds at the corners of the mouth (children with hereditary syphilis), and herpes labialis. (See p. 66.)

Teeth.—The condition and the time of appearance of the first and second sets are important in childhood.¹ In adults we should

¹ [Note irregular dentition as indicating nasal deformity and former adenoids.—Ed.]

notice the state of preservation of the teeth. Poor teeth not infrequently cause digestive disturbances. They are quite commonly due to some general disturbance. Special attention should be paid to

Fig. 322.—Irregular teeth simulating Hutchinson's teeth in a patient at the New York City Hospital, who exhibited at the time this photograph was taken a well-marked secondary syphilitic eruption.

so-called "rachitic teeth." They are characterized chiefly by transverse and longitudinal grooves with uneven enamel, which rapidly wears off

Fig. 323.—Irregular teeth in a young boy with a high arched palate. Although the two upper middle incisors are slightly wedge-shaped, there is not sufficient ground for considering them of the Hutchinson type. The irregularities are probably due to an inflammation of the gums during the second dentition (Dr. W. L. Stowell, Randall's Island Hospital).

on account of its irregular distribution. These changes are most marked in the incisors. In hereditary syphilis the teeth are often deformed, very much as in rachitis. Some of the dental deformities which are ob-

served in this disease are by no means characteristic of syphilis alone, but occur also in rachitis and other general disturbances, or even when the teeth-buds have been damaged by stomatitis. Hutchinson considers the type of teeth shown in Figs. 318 and 319 as pathognomonic of hereditary syphilis.¹ Other authors consider the concave notches in the

Fig. 324.—Irregular teeth, not Hutchinson's teeth (New York City Hospital).

lower margin of the upper middle incisors the characteristic feature (Fig. 318). The term "Hutchinson teeth" is applied more especially to those showing the latter peculiarity. These are observed chiefly in the second dentition. After the twenty-fifth year this concavity is usually worn away.

It is important to be familiar with the normal periods of the appearance of teeth, so as to be able to recognize anomalies in their appearance and to attach a

Fig. 325.—Sequences of teeth with first dentition (A. Vogel).

proper significance to the symptoms oftentimes connected with their eruption in early childhood.

A. Vogel makes the following statements (Fig. 325):

FIRST DENTITION.

First Group.—The two lower middle incisors appear almost simultaneously between the seventh and the ninth month.

Interval of three to nine weeks.

¹["Hutchinson's teeth" were first described in the Transactions of the Pathologic Society of London, July, 1858. In the original description he says: "There is a peculiar condition of the teeth resulting from hereditary syphilis, the most frequent conditions being the following:

"(a) *Smallness*.—They are small, stand apart, are rounded and peggy.

"(b) *Notching*.—They usually exhibit at the border a broad, shallow notch (sometimes two or three serrations).

"(c) *Color*.—They have a dirty-grayish surface without polish, and are rarely smooth.

"(d) *Wearing Down*.—They are deficient in enamel and are soft, and therefore liable to premature wearing down

"(e) These signs almost exclusively apply to the incisors and canines."—Ed.]

Second Group.—The four upper incisors appear between the eighth and the ninth month, and follow one another rapidly within a few weeks, first the middle and then the lateral ones.

Interval of six to twelve weeks.

Third Group.—Six teeth appear almost at the same time between the twelfth and the fifteenth month. These are the first four molars and the two lower lateral incisors. Usually the anterior molars of the upper jaw appear first, then the lower lateral incisors, and finally the anterior lower molars.

Interval to the eighteenth month.

Fourth Group.—The four canines appear between the eighteenth and the twenty-fourth month.

Interval of two to three months.

Fifth Group.—The four second molars appear between the twentieth and the thirtieth month. This ends the first dentition, and the child then has the 20 "milk-teeth."

SECOND DENTITION.

During this period the milk-teeth are supplanted by permanent teeth, and the three posterior molars in each jaw appear. The latter are not present during first dentition. A permanent set of 32 teeth then takes the place of the 20 milk-teeth. Second dentition begins in the fifth or sixth year of life, with the appearance of the first molar teeth in each side of the jaw. The milk-teeth now begin to fall out in the same order that they appeared. Each tooth as it falls out is supplanted immediately, or very soon, by the corresponding permanent tooth. The second molars appear during the twelfth year, and the third molars, or wisdom teeth, appear from the fifteenth to the twenty-fourth year, or sometimes still later.

Welcker's data differ somewhat from the above:

Table of Dentition According to Welcker.¹

Teeth.	First dentition. Months.	Second dentition. Years.
Proximal incisors.....	6 to 8	8
Distal incisors.....	7 to 9	9
Canines.....	16 to 20	11 to 13
Proximal premolars.....	12 to 15	10
Distal premolars.....	20 to 24	11 to 15
First molars.....		7
Second molars.....		13 to 16
Wisdom teeth.....		18 to 20 to 30

Gums.—The gums are swollen and bleed easily in acute and chronic mercury-poisoning, occasionally after the use of iodids and bromids, in scurvy, and in other hemorrhagic conditions. Acute lymphoid leukemia is to be especially kept in mind. (See p. 835.) The bluish-gray "lead-line" on the gums, due to a deposit of lead sulphid in the mucous membrane, is of great diagnostic importance in chronic lead-poisoning. This line should not be confused with a discoloration of the teeth themselves at the junction of the gums. The latter is not uncommon in careless individuals and those who smoke a great deal. This discoloration is visible up to the margin of the gum, and may simulate the blue appearance of a lead-line very closely. It is quite easy to distinguish these conditions by pushing the corner of a stiff piece of paper beneath the margin of the gum. A true lead-line will become more distinct than ever, but the apparent lead-line, caused by the shining of the discolored teeth through the margins of the gums, will disappear entirely. A bluish discoloration, due to venous congestion, sometimes appears at the margin of the gums, not only in general circulatory disturbances, but in some local inflammations of the gums, and may lead to error. The pressure exerted by employing the piece of paper as above directed makes the gum anemic and renders the distinction easy.

¹ Arch. f. Anthropologie, 1866, vol. i.

Tongue.—The way the tongue is protruded at command is sometimes more or less characteristic. Very ill or stupefied patients protrude a tremulous tongue, and leave it out until told to withdraw it. Bites of the tongue [or their scars.—Ed.] are of great diagnostic importance in epilepsy.

We should examine the tongue of patients with bulbar symptoms closely for any noticeable atrophy. This atrophy may become quite marked indeed in progressive bulbar paralysis, and the tongue may exhibit pronounced fibrillary contractions. Many healthy individuals, however, present a slight fibrillary twitching of the tongue.

The so-called "coat" of the tongue, caused by hypertrophy and other changes of the epithelium that as yet have been but insufficiently studied, is of some diagnostic importance. The tongue is coated in all dyspeptic conditions and in fever. This coating is usually associated

Fig. 326.—Lead-line: Note the interrupted, fringe-like line just at the edge of the gum (photographed from a water-color drawing) (kindness of Dr. R. C. Cabot).

with some disturbance in the appetite. Acute and chronic gastric catarrh is almost always associated with a coated tongue; but in ulcer of the stomach the tongue is often not coated, and there is no disturbance in the appetite. The causes of the epithelial changes leading to coating of the tongue are but little understood; there is, however, much evidence justifying the interpretations of the sign as a phenomenon of intoxication in the broadest sense of that word.

It is very often explained as being due to the fact that in people who do not eat, the lingual epithelium is not removed in a normal way by friction. This explanation, however, does not agree with clinical experience. Starvation does not result in a coated tongue.

According to L. Kurt,¹ this phenomenon appears in gastric disturbances in which he has demonstrated the return of food-elements from the stomach back to the mouth.

¹ Berlin. klin. Woch., 1906, No. 28.

Frequently in patients with high fever the tongue is not only coated, but dry, on account of the diminished secretion of saliva. Small fissures of mucous membrane are rather common in these cases and may cause some bleeding. The blood-crusts which form in this way, combined with the dried brownish epithelium of the tongue, produce a dark-brown or blackish, the so-called fuliginous, coat. This always indicates that the patient's condition is serious. It may be found on the lips at the same time.

The coating of the tongue is often stained by certain food-stuffs, drinks, or medicines (milk, red wine, coffee, cocoa, chocolate, licorice, [fruit, tobacco.—ED.] etc.).

The presence of fungi must not be confused with an ordinary coating of the tongue. Fungi may be found on the tongue, as well as elsewhere on the mucous membrane of the mouth, and occur in the form of large thick patches. Fresh patches are easily recognized by their snow-white color and rounded outline. The older patches often lose this white color, and are of a peculiar dirty-gray appearance. The situation of these mycotic patches on the margin of the tongue, their appearance in other parts of the mouth, and their solid character distinguish them from a simple coated tongue. Fig. 291 represents the microscopic appearance of thrush.

The tongue should be examined for *aphthous patches* and *syphilitic sores*. The peculiar circular thickenings of the epithelium, with slight inflammatory signs, so-called "*leukoplakia buccalis*," must not be confounded with either of them. Leukoplakia, sometimes called "*psoriasis linguæ*," is much more extensive. Its nature is not as yet well known. In one such case the author found large numbers of pneumococci in the thickened epithelium. Whitish, thickened spots of epithelium, produced by the irritation of bad teeth or of too much smoking, may resemble syphilitic mucous patches very closely.

The nature of the so-called *black, hairy tongue* is utterly unknown.

The erythematous tongue of scarlet fever, with its red and swollen papillæ, is very characteristic. It is familiarly known as the "*strawberry or raspberry tongue*."

[Virchow's smooth atrophy of the base of the tongue¹ may be of some value in diagnosing late syphilis. It consists of an atrophy of the lingual tonsillar tissue, and can be appreciated by palpation better than by inspection.—ED.]

Soft Palate; Tonsils; Pharynx.—The various kinds of acute angina are to be considered in this connection (*angina simplex, follicularis, necrotica, phlegmonosa*, and *diphtheritica*); furthermore, the different varieties of chronic pharyngitis (*pharyngitis sicca, granulosa*, etc.). (See text-books of Special Pathology.) In the author's clinic cases of diphtheria are examined according to the plan to be found in the appendix; this plan was likewise used in the diphtheria investigation carried out by the Swiss government.

Examination for Diphtheria Bacilli.—In doubtful diphtheric membranes only a microscopic demonstration of Löffler's bacilli (see Fig. 327) will prove the existence of true diphtheria. These bacilli are sometimes found in the membrane of true diphtheria in great numbers. Dry preparations may be made from the membrane in the same manner as described for the sputum, and then stained with the ordinary anilin stains, preferably by Gram's method. But cultures are generally

¹ Potter, Boston Med. and Surg. Jour., vol. cliv, No. 10, p. 260.

necessary. According to the investigations of the Bacteriologic Institute at Bern,¹ Löffler's horse-serum and glycerin-agar (7 per cent. glycerin) slants are the best media for growing diphtheria bacilli.

The media can be inoculated from the surface of the affected region of the pharynx by means of a sterile platinum loop [or a swab.—Ed.]. The round colonies of diphtheria bacilli, transparent at first, gradually become opaque. They may be seen after the tube has remained in an incubator about twelve hours. The colonies must be identified by preparing and examining microscopic slides, as macroscopically

Fig. 327.—Diphtheria bacilli ($\times 1000$) (after Weichselbaum. Culture).

they may be confounded with those of other bacteria, especially streptococci. It is diagnostically important to remember that diphtheria bacilli are generally present in the pharynx in cases of laryngeal diphtheria, even when the pharynx itself is not visibly affected.

THE PRACTICAL VALUE OF THE BACTERIOLOGIC EXAMINATION FOR DIPHTHERIA

Diphtheria may be recognized clinically with a considerable degree of accuracy in the vast majority of cases, although demonstrating the presence of diphtheria bacilli may be very important.² Where there are clinical reasons for making a diagnosis of diphtheria (epidemics), we should not rely absolutely upon the result of a single negative bacteriologic examination (even when Löffler's modified serum is used). The author can cite numerous cases in which a single bacteriologic examination in the hands of experts was negative; yet diphtheria bacilli were discovered after repeated examinations and thus the early clinical diagnosis fully confirmed.

Negative results may easily be due to accidental conditions in inoculating the medium; or, in case the diagnosis is made to depend upon the result of cultures and the specimen is sent to a central laboratory, it must be remembered that the bacilli may have become less viable from drying. Again, other bacteria may easily outgrow the diphtheria bacilli in the culture-tube. The use of antiseptics (gargling, swabbing) in diphtheria is often responsible for a negative culture. Finally, for unknown reasons, certain diphtheria bacilli (discovered in the Bacteriologic Institute at Bern)³

¹ G. Michel, *Das Wachstum der Diphtheriebacillen auf verschiedenem Serum und Glycerinagar*, I. D., Bern, 1897 (Centralbl. f. Bakteriologie). The writer concludes that Löffler's modified horse serum is the best medium of the five he examined, and that glycerin-agar is next. Löffler's ox serum and the pure ox or pure horse serum, without any addition, are considerably inferior. These results suggest that any statements in literature regarding false diphtheria are doubtful. Even the highly recommended Löffler's modified horse serum frequently gives a negative result, whereas, from the same case, diphtheria bacilli grew on one or the other inferior medium. Perhaps the most logical conclusion is that one negative examination does not prove anything.

² Deucher (Bern), *Zur klin. Diagnose der Diphtherie*, *Correspondenzbl. f. Schweiz. Aerzte*, 1895, No. 16, p. 485.

³ Michel, *loc. cit.*

refuse to grow well upon the media which is generally supposed to be best. Allowances are not made for these circumstances (chances), and the capricious action of the diphtheria bacilli in the ordinary bacteriologic examination. Control examples have proved beyond doubt that these factors may influence the result of bacteriologic examination. A physician may err if he relies absolutely upon the bacteriologic examination, especially if attempted only once. Since the introduction of serum treatment this is a serious matter, from a therapeutic standpoint, and it may be still more disastrous from a prophylactic one.

A positive result, especially if results of cultures be exclusively depended upon, must also be carefully interpreted, for we know that virulent diphtheria bacilli are not infrequently found in perfectly healthy people, in ordinary cases of mild coryza and rhinitis, and in cases of pharyngitis which do not even produce a rise in temperature. It is hardly justifiable to administer antitoxic serum in these cases, because, as is well known, its use does not remove the bacilli. It is perfectly possible that at some later date a severe case of diphtheria may develop in the individual. *A logical and practical deduction is that the serum treatment should not be confined to cases where the bacteriologic examination is positive, but should be employed whenever the case presents a perfect clinical picture of diphtheria, or when there are severe symptoms and diphtheria bacilli are present in numbers, although the case may not resemble diphtheria clinically.*

The bacteriologic examination would be of much greater clinical value if in every case smears could be made directly from the pharynx, then fixed, stained, and examined under the microscope whether cultures are simultaneously made or not. The chief error in the modern culture method is that mere chance in inoculation may alter the results of cultures and the numeric relation of the bacteria, so that some species may be entirely suppressed. In one case the diphtheria bacilli may be overgrown by other bacteria and totally overlooked, and in another a few diphtheria bacilli may overgrow everything else, although in the actual illness they may be of little or no etiologic significance. In a dry preparation the conditions are represented as they actually exist. In the bacteriologic diagnosis of the upper air-passages, just as in the bacteriologic diagnosis of peritonitis or cystitis, culture results may be misleading so far as etiology of the affections is concerned. It seems probable to the writer that when dry preparations are granted their proper place in the diagnosis of angina, contradictions between clinical conditions and bacteriologic examinations will, for the most part, disappear. But the seat from which a dry preparation is made must be selected far more intelligently than in the present culture examination method—that is, when the diseased region is easily accessible, a slide must be prepared from it, and when diphtheria is in the larynx alone, more than the saliva must be examined. Especial attention should be paid to the tonsils and to the fossa between the pillars of the fauces. Sometimes it may be necessary to make several preparations, just as it is in the examination of sputum for tubercle bacilli. In making cultures, the importance of selecting the proper regions is often forgotten. In addition to the factors already mentioned, this neglect may explain the unsatisfactory lack of harmony between the clinical diagnosis and the bacteriologic examination. Dry preparations made from material sent for examination do not always fulfil the above demands, because the material may not be suited for microscopic examination.

The occurrence of diphtheria bacilli in the throats of healthy people or of those without clinical diphtheria or without croup has caused a great deal of confusion. The name pseudodiphtheria bacilli has been applied to such organisms. Morphologically they are quite similar to true diphtheria bacilli, that is, they show clubbed forms, have the same biologic and staining characteristics, etc., but do not possess the specific property of causing diphtheria, having been found in cases in which clinically no diphtheria was present. Every possible petty characteristic has been seized upon by which these bacilli could be distinguished from the true diphtheria bacilli in spite of the very great semblance between the two.

Virulence can be tested upon animals only after the bacteria have been altered biologically by making cultures. Hence it is clear *a priori* that animal experiments do not prove anything regarding the bacterial virulence in man. Besides, it has even been demonstrated that diphtheria bacilli taken from the buccal cavity of healthy people, although usually considered pseudodiphtheria bacilli, may sometimes be just as virulent for animals as true diphtheria bacilli taken from patients suffering from clinical diphtheria. The different influences of diphtheria serum upon animals inoculated with true and false diphtheria cannot be used as a differential point, because such a differentiation begs the question, taking it for granted that the cultures which act differently to the serum must of necessity belong to different

species. The numerous efforts¹ to separate the pseudodiphtheria bacilli from the true bacilli have been absolutely fruitless. It seems to the author better to assume that the variable significance of diphtheria bacilli for man is due to individual difference in species and to the continuous changes in varieties produced by repeated inoculations; and that such efforts to distinguish between true and false diphtheria bacilli by their morphology will probably never succeed.

Another point of distinction is the double stain recommended by M. Neisser.² He found that if dry specimens be prepared from a Löffler's serum culture ten to twenty hours old at 35° C., stained for one to three seconds with acetic acid-methylene blue,³ washed in water, and then stained with aqueous Bismarck brown⁴ for three to five seconds, certain isolated chromophilic portions of the organisms, the so-called polar bodies, stain blue. He claims that true diphtheria bacilli exhibited this peculiarity, but not the pseudobacilli.

This is in itself very interesting; but it is quite incomprehensible to the author that these writers fail to recognize that they argue in a circle in all these endeavors to discover points of differentiation between true and false diphtheria bacilli. Because the older differential characteristics have proved unreliable, they unconsciously fall back upon the clinical diagnosis by demanding that the true diphtheria bacilli must come from a case that is clinically diphtheria. Neisser's results, we believe, prove nothing more than that the polar stain is present in serum cultures made from clinical diphtheria, but is absent in cases which cannot be considered diphtheria from a clinical standpoint (healthy people, follicular tonsillitis, and

doubtful clinical cases). According to the author's opinion, this peculiarity does not prove anything about the differentiation between true and false diphtheria bacilli, nor does it indicate the diagnosis in any given case. In typical cases there is no need of this criterion. The test does not decide whether these diphtheria bacilli, called false by Neisser, are anything more than varieties of so-called true diphtheric bacilli. Biologic variations responsible for the lack of a clinical picture of diphtheria may, of course, be equally responsible for the absence of his reaction. The cause of the variations may depend on the peculiarities of the medium or the susceptibility of the patient. Neisser considers his stain is available only for very young cultures upon Löffler's serum, which, of course, means that this criterion is not adapted to differentiate variations of species. The fact that this staining reaction is not trustworthy in dried preparations direct from the throat, and the emphasis

Fig. 328.—Dried smear of exudate in Vincent and Plaut's angina. Fusiform bacilli and spirochetes ($\times 500$) (after Reiche).

placed upon the age of a culture, as well as the statement that false diphtheria bacilli, when old, may react in the same way, show how little value the method really has.

Although the author does not consider the demonstration of Neisser's polar bodies sufficient for the differentiation between pseudodiphtheria bacilli and the true bacilli, yet he does not deny that these bodies are very valuable in differentiating morphologically diphtheria bacilli from other bacteria, much as the demonstration of capsules is of use in demonstrating pneumococci. The latter demonstration, likewise, is not always successful.

Virulent diphtheria bacilli may be found in the fluids of the mouth months after the disease has run its course. Theoretically, this fact is very important for prophylaxis, but the practical difficulties are too great. In the first place, it would be almost impossible to isolate every convalescent from diphtheria until the throat examination was negative, and, in the second place, in view of the frequent occurrence of the diphtheria bacilli in healthy individuals' throats, such isolation would hardly be warranted.

The presence of streptococci and staphylococci is of interest in the etiologic study of different types of angina. They may often be present at the same time with

¹ See C. Fränkel, Die Unterscheidung der echten und falschen Diphtherie-bacillen, Berlin. klin. Woch., 1897, p. 1087, No. 50.

² Zeit. f. Hyg., 1897, vol. xxiv.

³ One gm. of methylene-blue (Grübler) dissolved in 20 cc. of 96 per cent. alcohol and then 950 cc. of distilled water and 50 cc. of glacial acetic acid added.

⁴ 0.2 gm. Bismarck brown dissolved in 100 cc. boiling distilled water.

diphtheria bacilli (Figs. 281 and 285). Fränkel's pneumococcus (Fig. 281), the *Micrococcus tetragenus* (Fig. 287), the *Micrococcus conglomeratus*, and several others may also occur. Mention must be made of *Bacillus fusiformis*, which, together with a peculiar spirocheta, forms the bacteriologic characteristic of the so-called Vincent's or Plaut and Vincent's angina; this affection sometimes simulates diphtheria by the presence of a pseudomembrane; at other times is accompanied by the formation of ulcers. These organisms have not yet been grown in pure culture. The fusiform bacilli are gradually decolorized by Gram's method. The spirochetæ are Gram-negative.¹ All these bacteria frequently inhabit a normal mouth, so that little importance can be attached to their demonstration by culture methods as compared with the demonstration of their presence, in large numbers, in freshly prepared dry slides. (Regarding the method of preparation, see p. 715.)

THE DEMONSTRATION OF SPIROCHÆTA PALLIDA IN SYPHILITIC LESIONS

[The demonstration of *Spirochæta pallida* in syphilitic lesions of the mouth and pharynx, as well as of other parts of the body, may be mentioned here. The following is the technic of White and Avery,² using Schereschewsky's stain: The lesion is thoroughly cleansed by wiping with gauze. The junction of the necrotic and sound tissues, as well as a part of the floor of the ulcer, is then scraped with a small curet or scalpel until the superficial tissue is removed and a slight flow of blood is produced. The lesion is then sponged with dry gauze until the blood has ceased to flow and clear serum is seen to ooze. A drop of this serum is then spread on a perfectly clean glass slide in the thinnest possible uniform film. Smears so obtained are allowed to dry in the air and then passed through the flame three times. The staining fluid is freshly prepared by adding 13 drops (from a dropping-bottle) of Giemsa's solution (Grübler) to 10 cc. of a 0.5 per cent. watery glycerin solution. The mixture is then heated to boiling, immediately poured on the slide, and allowed to remain for from three to five minutes. The stain is then poured off and the slide washed with neutral distilled water. The slide is dried by shaking it rapidly through the air, and a second application of the stain is made for the same length of time. As a rule, two applications suffice to impart to the smear a distinct pinkish tinge. Should the pink be too faint, a third application is made. When the desired shade is reached, the slide is washed as above and dried by shaking or with fine blotting-paper (Royal). The preparation is then examined with a one-twelfth mm. oil-immersion lens. In order to obtain ideal results certain precautions must be heeded. All vessels with which the stain comes in contact must be perfectly clean. Before mixing each fresh lot of stain the test-tube used should be cleansed by scrubbing with clean cotton and alcohol, then rinsed with distilled water. Any deposit of stain about the neck and lip of the dropping-bottle should be removed by carefully wiping with filter-paper. The water used in making the glycerin solution and for washing the slide should be neutral, as the least degree of acidity causes the formation of a precipitate. Should any of these precautions be neglected, it will be found that a heavy bluish precipitate forms in the mixture on boiling and its staining ability is thus impaired. The exact tint of the smear to be obtained is a matter of no great importance and is easily determined. After a few trials, in which the importance of the above details is realized, one may expect to produce satisfactory preparations.

In preparations thus stained the *Spirochæta pallida* should appear a deep pink, with the background pale in comparison. It is a delicate, spiral-shaped organism, 4 to 14 μ in length and less than 0.25 μ in breadth. The ends are somewhat pointed. The convolutions number 6 to 14 or over. The *Spirochæta refringens*, frequently found in suggestive lesions, is to be distinguished by its greater width and by the relatively few convolutions.

Staining with *Goldhorn's solution*³ is very simple and yields excellent results. The stain is dropped on the unfixed preparation and left for a few seconds. The

¹ For particulars about the fusiform bacilli and the spirochetæ that usually accompany them, as well as about the clinical picture of Vincent's angina, see Plaut, *Deut. med. Woch.*, 1894, p. 922. Vincent, *Ann. Past.*, 1896, p. 488, and 1899, p. 609. Reichs, *Jahrb. d. Hamburgischen Staatskrankenhäuser*, 1903-04, vol. ix; also J. Douglas Blackwood, *Proceedings of the Pathological Society of Philadelphia*, 1906, No. 4, p. 103.

² White and Avery, *The Treponema Pallidum*, *Arch. of Int. Med.*, June, 1909.

³ *Proc. New York Path. Soc.*, 1905, No. 5, p. 169.

slide is then slowly immersed in water, film side down, held so for four to five seconds to allow interaction between the water and the dye, and is then moved about in the water to wash it. It is then stood on end to drain and allowed to dry without the use of filter-paper or heat.

Hasting's stain may be used for smears made from the serum which exudes from syphilitic lesions. The technic is the same as for blood. (See p. 780.)

The so-called *India-ink method*¹ is perhaps the simplest and most satisfactory for demonstrating the organism. A loopful of serum, obtained from a syphilitic lesion in the manner described above, is mixed with a drop of the best obtainable commercial Chinese ink (Günther and Wagner's or Higgins' India ink) and spread out on the slide in the thinnest possible uniform layer, just as in making blood-smears. It is allowed to dry and can then be examined directly with an oil-immersion lens. The field is a homogeneous brownish yellow. Blood-cells and spirochætae appear luminous white. Everything else is covered and hidden by the ink.

Should doubt arise concerning the specific nature of the organism found by the above methods of examination, the material should be examined in the fresh state, best by means of the dark-field illuminator (Reichert, Vienna). A drop of the serum is placed on a cover-slip and this is inverted on a slide 1 mm. thick. Both must be absolutely clean, and care must be taken to prevent the formation of bubbles. The spirochætae, as well as other bacteria and the leukocytes, appear luminous on a black field.

Cultivation of Spirochæta Pallida.—Schereschewsky² has succeeded in securing a growth of the spirochæta at 37° C. in from three to five days on horse serum, which had been brought to gelatinous consistence and subjected to partial autolysis by standing about three days in a thermostat at 37° C. Inoculation of the growth so obtained into animals has not, however, proved successful.—Ed.]

Retropharyngeal abscesses present a visible and palpable swelling in the posterior pharyngeal wall. They may cause dyspnea. *Hypertrophied tonsils* are evident to inspection. *Adenoids* can be felt in the nasopharyngeal space. (See p. 869.) The mobility of the soft palate should also be noted. For a *paralysis of the palate* or for *absence of the palate reflex* (hysteria), see section upon Rhinoscopy and Laryngoscopy (pp. 897 and 904).

Direct Rhinopharyngoscopy.—W. Lindt,³ of Bern, has recently described a method for direct inspection of the nasopharyngeal space. This is accomplished by pulling the soft palate forward and upward by means of the palate hook depicted in Fig. 329.⁴ With the illumination from an ordinary head-mirror, the posterior, lateral, and upper wall of the nasopharynx can thus be examined, and most easily if the head be bent slightly backward. The anterior and posterior walls of the soft palate must be cocaineized (2 to 4 per cent. solution) in

Fig. 329.—Lindt's palate hook for direct rhinoscopy.

sensitive individuals. (See p. 899.) This method of examination is valuable especially for the purpose of detecting adenoids.

Hard Palate.—We should look especially for syphilitic perforation of the palate [for mucous and mycotic patches.—Ed.], and in children for the so-called Bednar's aphthæ.

Buccal Mucous Membrane.—Besides the conditions of the mu-

¹ R. Frühwald, Ueber den Nachweis der Spirochæta pallida mittels des Tusche Verfahrens, Münch. med. Woch., Dec., 1909, p. 2523.

² Deutsch. med. Woch., July 22, 1909.

³ Die directe Besichtigung und Behandlung der Gegend der Tonsilla pharyngea und der Plica salpingopharyngea in ihrem obersten Theile, Arch. f. Laryngologie, vol. vi, p. 1

⁴ Made by Klöpfer in Bern.

cous membrane described in connection with other portions of the mouth, we may look for cancrum oris, stomatitis, etc. A rare gangrenous condition of the mucous membrane of the cheek called *noma* is sometimes found in children. Koplik's spots, an early sign in measles, should also be remembered. (See Plate XI.)

Secretion of Saliva.—Increased salivation accompanies all types of stomatitis and chronic mercury-poisoning. (In one of the author's cases this persisted for six months after a single dose of calomel.) The secretion of saliva is diminished in *fever, diabetes mellitus, cholera, atropin-poisoning*, and in *facial and bulbar paralysis*.

Examination of Saliva for Mercury for the Prevention of Mercurial Stomatitis During Treatment with Mercury.—Severino¹ says that the mouth secretions during administration of mercury give, on addition of tincture of iodine, a red color, due to the formation of mercury biniodide only in case the organism is oversaturated with the metal. In such an event it seems advisable to interrupt the use of mercury in order to prevent symptoms of poisoning with the drug, and especially the appearance of a stomatitis. Severino has devised a simple method of carrying out this test. He paints the anterior surface of the incisor teeth with tincture of iodine and then asks the patient to wet the teeth thoroughly with saliva. In case the reaction is positive, a more or less intense rose-colored stain appears on these teeth within half a minute.

EXAMINATION OF THE ESOPHAGUS

In the diagnosis of diseases of the esophagus we should be on the watch for disturbances in function, for pain upon swallowing, signs of stenosis or regurgitation, in addition to the direct method of examination about to be described. We must differentiate between regurgitated material from the esophagus and vomitus (p. 431). The surgical rules for palpation apply to the external examination of the cervical portion of the esophagus. One should look out for tumors which compress the esophagus, for swollen glands, for goiters, for sensitiveness along the course of the esophagus, etc. Diverticula of the esophagus are characterized by their variations in volume and by the fact that they can be emptied.

Esophageal Sounds or Tubes.—The well-known whalebone sounds, to the tip of which an ivory olive of varying caliber may be screwed or the English elastic tubes of varying caliber are employed. Before introducing one of these instruments we should be sure that they are in perfect condition, as a faulty instrument may sometimes injure the patient.

For certain purposes we make use of specially constructed sounds, such as those devised for the examination of diverticula. These sounds are so designed that it is possible to curve them in any direction after introducing them into the esophagus; in one case the physician is enabled to direct the sound into a diverticulum in order to examine it thoroughly; in another, in which ordinary sounds would enter the sac, he can slip past, either for the purpose of diagnosis or for feeding the patient through the sound.

Fig. 330 shows a longitudinal section of the tip of Zenker and Leube's diverticulum sound, that has been used for a long time for this purpose. The essential portion of this sound consists of a peculiarly constructed obturator, which contains

¹ La Sem. méd., 1906, p. 186, No. 16.

two parallel wires gliding through wire rings. The figure shows how the movement of these wires curves the jointed end of the obturator, and with it the tip of the sound. This obturator is introduced inside the lumen of an ordinary stomach-tube. One wire ends in a ring outside of the stomach-tube, and the other has a

Fig. 330.—Longitudinal section of the tip of Zenker and Laube's diverticulum sound.

Fig. 331.—The tip of the obturator in author's diverticulum sound.

cross-piece attached to its end, so that the operator can give any desired curve to the tip of the sound by manipulating the wires by means of these attachments. The author has constructed a very simple diverticulum sound designed upon a different principle. The essential part of this instrument, too, consists of a peculiarly constructed obturator, which is also used with a common stomach-tube. (See Fig. 331.)

The obturator is made just like an olive-pointed bougie, from a piece of whalebone that is stiff and yet flexible. At its tip is attached a slim and rather flexible nickel-plated spring, terminating in an eccentrically placed cone made of German silver. The obturator is introduced into a rather thin stomach-tube with lateral fenestrations, which must be provided with a hollow blind tip beyond the fenestrations, so that the metal cone of the obturator may be fitted tightly into it. If the tube have no such tip, it may be made by burning out the solid tip with red-hot wire. The concavity of the spring and the projection of the metal cone should be directed to the side toward which the tube is to be bent; and the direction of the curve in the spring is marked upon the handle of the obturator.

If the operator push the obturator forward while holding back the stomach-tube, the latter must bend at the portion corresponding to the steel spring of the obturator and curve in any desired direction and to any desired degree. In addition to its simplicity the author's instrument possesses still another advantage, for when bent, it assumes a gradual curve and not a sharp angular one; moreover, its tip always retains a certain elasticity and softness. The author suggests the application of

this principle in the construction of urethral catheters, such as those used in prostatic hypertrophy.

The author's dilating sound was designed for therapeutic purposes, more especially for gentle dilatation of the esophagus in spasm at the cardia, the most frequent

Fig. 332.—The author's dilatation sound.

cause of spindle dilatations of the esophagus. However, it may be used for diagnostic purposes, as, for instance, to prove the dilatability of such spastic stenoses or for examining tuberculous bronchial glands. (See p. 896.) The instrument consists of a whalebone sound with a peculiar tip. (See Fig. 332.) Instead of the usual ivory olive, the author substitutes a German-silver one, *b*, which is provided with a canal that opens upon the surface of the olive by means of two perforations, *e*, and by means of a third, *d*, upon the surface of a metal link connecting the olive and the staff. For use, the metal olive is unscrewed, the whalebone staff is passed through a rather narrow stomach-tube, *g*, provided with a terminal central opening, and its tip allowed to project a little. The olive is then screwed on, covered with a rubber nipple, *f* (medicine-dropper); and the end of the stomach-tube is firmly tied over its free border. In the figure the rubber parts of the complete instrument are depicted by dotted lines, while the curved line, *h*, represents the ligature just described. The handle of the staff is likewise made removable, so as not to interfere with the following manipulations: Air blown into the interior of the rubber tube by means of a bulb is forced into the perforation, *d*, and then escapes through the perforations, *e*, into the rubber nipple, expanding the latter to any desired degree. The rubber tube, being provided with much thicker walls, is hardly affected by the air. The apparatus is connected with the air-bulb by means of a piece of glass tubing over which the end of the rubber tube is slipped, while the end of the whalebone staff, minus its handle, projects into the lumen of the glass tube. If the latter be provided with a lateral arm, a mercury manometer may be interpolated, so that, during the operation, the pressure exerted at the site of the obstruction may be estimated. If considerable pressure must be used, the olive may be covered with two rubber nipples. A single nipple is easily overdistended, balloons out into a large bag when in this condition, may burst suddenly, and the pressure it exercises upon the stenosed part is quite indeterminable. The author considers this dilating sound much to be preferred to those described in the literature, which are often difficult to obtain.

The technic of introducing these relatively stiff sounds differs somewhat from that employed in the use of soft stomach-tubes. (See p. 440.) The following is the best mode of procedure.

The esophageal bougie is held in the right hand, close to the end, very much like a pen; the tip is smeared with oil or glycerin, and the patient, in the sitting posture, is told to open his mouth and bend his head well back. The tip of the bougie, covered by two fingers of the left hand, is introduced into the pharynx, and pressed slightly forward. It is kept as nearly as possible in the median line. This position of the head has the advantage of placing the esophagus in the direction of the axis of the mouth, but if the introduction of the sound prove impossible, in spite of it the head of the patient should be inclined slightly forward. When the head is thrown backward, the cricoid cartilage is pressed backward too, and may interfere with the passage of the tip of the sound into the esophagus. However, individual patients differ in this respect, and the best thing to do is to control the head of the patient with the left hand during the introduction of the sound and bend it according to the resistance met with. It is most important that the sound should not deviate from the median line while being introduced; otherwise it may easily be caught in one of the pyriform sinuses. After overcoming the slight physiologic resistance at the level of the cricoid cartilage, the bougie will pass as far as the stomach with ease, provided there is no pathologic obstruction. Efforts to swallow are best avoided, as they are unnecessary and only induce gagging, on account of the contact of the soft palate with the bougie. It is important for the patient to breathe regularly. (See Stomach Examination, p. 441.) If the examiner be awkward, or if there be a paralysis or lack of sensation in the pharyngeal region, a hard bougie will enter the larynx more readily than a soft one. But this fault can be avoided easily if the point of the bougie, while

being introduced, be allowed to pass along the posterior wall of the pharynx. When hard hollow sounds are employed, a peculiar whistling respiratory noise arises on introduction (p. 441). An inexperienced operator may be alarmed by this, believing that the tube has entered the larynx. The noise is in reality produced by the respiratory variations of pressure in the interior of the thorax, which are transmitted in sufficient strength to the esophagus to produce an in-and-out current of air through the sound, unless its opening be occluded by the esophageal wall (esophageal breathing). This can be easily demonstrated by placing a burning candle before the end of a stomach-tube in position. The flame will flicker regularly with respiration. The greater size of the hard tubes and their resonance probably explain why this sound is much more intense when these are employed than when soft ones are introduced. The moment the tip of the sound enters the stomach, this noise ceases. If the sound enter the larynx, dyspnea almost always follows, and, unless the larynx be anesthetized, violent attacks of coughing and severe pain.

Kraus claims, however, that in less sensitive individuals the sound may be introduced into the larynx without causing any reaction. This is to be kept in mind especially in cases of paralysis of the gullet. In case of doubt it is easy to make sure that the sound is in the right place by palpation, using the epiglottis as a landmark. It must be said, however, that the introduction of an esophageal sound into the larynx is a very difficult feat, and the fear of such an accident is, for the most part, only theoretic. The existence of Zenker's diverticula forms an exception, the entrance to the esophagus being obstructed even at the level of the larynx. Introducing a sound into the larynx, in addition to causing injury to the parts, may be still more dangerous if fluids are poured through the tube, either for feeding the patient or for special diagnostic purposes (see below). However, this is generally done only after the operator has made sure of the position of the sound.

Esophageal sounds will demonstrate the presence of stenoses by transmitting a sensation of resistance to their advance. The most frequent cause of stenosis of the esophagus is carcinoma; then come diverticula, foreign bodies (bits of bone, false teeth, coins, etc.), syphilitic strictures, strictures from burns, compression of the esophagus from without by goiters, tumors, or aneurysms of the aorta, etc.

With signs of stenosis of the esophagus it is a good plan to attempt a working diagnosis regarding the nature of the disturbance before passing the sound, taking the history and the general condition into consideration. If aneurysm of the aorta be suspected, the sound should not be passed.

The sound, particularly by indicating the location of the obstruction, may throw some light on the nature of the stenosis. The following data should be remembered:

Distance from the incisor teeth to the uvula = 7 cm. (2½ in.).

Distance from the incisor teeth to the beginning of the esophagus = 15 cm. (6 in.).

Distance from the incisor teeth to the tracheal bifurcation = 23 to 25 cm. (9 to 10 in.).

Distance from the incisor teeth to the cardiac orifice = 40 cm. (16 in.).

The beginning of the esophagus lies at the level of the cricoid cartilage or of the sixth cervical vertebra, with the head midway between flexion and extension.

[The tracheal bifurcation (crossing of esophagus and the left bronchus) lies at the level of the fourth or fifth dorsal vertebra. The cardiac orifice lies opposite the spine of the twelfth dorsal vertebra or at the origin of the twelfth rib.—ED.]

Length of the esophagus = 25 cm. (10 in.).

Length of its abdominal portion = 2 cm. ($\frac{3}{4}$ in.).

Other landmarks in the topographic anatomy of the neck may be mentioned here. The spinous process of the second cervical vertebra lies 2 cm. below the external occipital protuberance. It is, however, not always to be felt. The dorsum of the tongue is at the level of the middle of the second cervical vertebra.

With the help of these figures it is easy to determine approximately the site of the obstruction, by measuring the length of the sound introduced until resistance is encountered. It is to be remembered, however, that they are but the average measurements for normal adults, and vary somewhat according to the stature of individual patients. It is, therefore, always advisable to study the site of an obstruction still further by placing the sound externally along the patient's neck, holding it in the same position as it may be supposed to have assumed within the esophagus, and again noting the level reached by the tip of the sound.

The consistence of an obstruction is also of considerable importance. It may be shown by the feeling or the noise produced by contact of the sound, especially if the whole bone sound be used against a hard foreign body, such as pieces of bone, coins, etc.

It is also important to determine the degree of stenosis. This is accomplished by trying a series of sounds of decreasing caliber until one is found sufficiently small to slip through the obstruction. In the patient's interest we should not employ any force while making this attempt.

It is also necessary, if possible, to estimate the length of the obstruction. This is very difficult to determine with the ordinary stomach-tube, but quite simple if the obstruction be permeable with the whale-bone sound. For this purpose the latter is furnished with an "olive" (of ivory or bone) which can be screwed or fastened over one end of the sound. Varying sizes of "olives" are necessary, so that one can be selected which will pass through the obstruction. After slipping by the obstruction the sound is withdrawn until the lower edge of the obstruction can be plainly felt; then, by comparing the position of the upper and the lower edge of the obstruction, we can readily determine its vertical extent. In the same way multiple obstructions can be located and measured.

Repeated examinations of an esophageal stenosis sometimes reveal this peculiarity—at one attempt the obstruction can be overcome very readily, while at another it is very difficult or quite impossible. Perhaps this depends upon the fact that the esophagus may alter its condition quickly, due to the destruction of ulceration or to the presence of food residue. Frequently, however, it depends upon some dilatation of the esophagus above the stenosis, so that the sound slips into a sort of pocket, and perhaps does not always meet the obstruction in exactly the same way. It may also be due to spasm of the esophagus, which may be added to the anatomic obstruction by the irritation in sounding. It is also possible that a saccular "pressure diverticulum" crowds against the esophagus, and when filled, compresses its lumen,

and so stops the sound, although, when the diverticulum is empty, the sound readily slips by. However, before assuming the existence of such a diverticulum, we should always bear in mind that the saccular "pressure diverticula" are found almost exclusively in the neck at the uppermost part of the esophagus, and if filled, are usually palpable externally; the so-called deep-seated pressure diverticula are very rare. Traction diverticula, which occur more frequently in the lower part of the esophagus, cause no stenosis.

In sounding the esophagus the exhibition of a localized tenderness at the moment when the tip of the sound passes over a definite place is of considerable diagnostic importance. Such a painful condition is observed in *carcinoma of the esophagus* and of the *cardiac orifice of the stomach*, even when there is no stenosis, in *inflammatory changes of the esophagus*, *esophagitis*, and in the rare *circular ulceration of the esophagus and of the cardiac orifice*.

With every attempt to sound the esophagus we should always carefully examine the sound as soon as it is withdrawn, and especially the fenestra at the tip of the stomach-tube if the latter be employed, in order to determine whether any fragments have been scraped off. Small bits of tissue not infrequently adhere in cases of carcinoma of the esophagus, and are often large enough to be sectioned after hardening in formalin, or with the aid of the freezing microtome. (See p. 516, note.) In this way the diagnosis of carcinoma may sometimes be confirmed. In "thrush" involving the esophagus, the fungus elements may be demonstrated microscopically in particles adhering to the withdrawn sound. (See p. 723, Fig. 291.) The fenestra of the sound frequently contain bloody mucus in carcinomatous and non-carcinomatous ulcerations of the esophagus. (For special findings in cases of carcinoma, diffuse dilatation, and diverticula of the esophagus, see p. 893.)

AUSCULTATION OF THE ESOPHAGUS

Other methods of examining the esophagus are subordinate to the methods of palpation and of sounding. *Auscultation of the esophagus* has thus far furnished rather barren results. Hamburger and Zenker auscultate the swallowing murmur in the neck upon the left side of the trachea, and in the chest to the left of the spine, at the level of the eighth dorsal vertebra. Here, during the act of swallowing, we can hear a peculiar clucking and hissing murmur. With pronounced esophageal stenoses the swallowing murmur may either disappear entirely or may be delayed from the level of the stenosis downward. Rewidzoff¹ has recently shown that the murmurs of swallowing described by Hamburger may be used in still another fashion in the diagnosis of esophageal stenosis. He auscultated the esophagus of patients suffering from stenosis at the level of the obstruction, first having them swallow a little water and then repeat the act of swallowing with an empty mouth; five to fifteen seconds after such acts of swallowing a hissing murmur could again be heard, some of the swallowed water having been retained above the obstruction in the first act, and passed through the obstruction by the subsequent acts of swallowing. Rewidzoff has termed these sounds *residual murmurs*, and speaks of the first, second, third residual murmur, etc. Meltzer² studied more minutely the murmur which arises upon the entrance of nourishment into the stomach, and which we hear best by auscultating the cardia with the stethoscope in the angle between the xiphoid process and the left costal margin. He arrived at the following conclusions: In normal individuals, six to seven seconds after the beginning of a single act of swallowing fluid or gruel, we hear at that point a more or less distinct prolonged murmur, as if the air or fluid were being squeezed through a sphincter-like obstruction (squeezing murmur). According to Kronecker and Meltzer's examinations, fluids are

¹ Rewidzoff, Berlin. klin. Woch., 1908, No. 15.

² Centralbl. f. d. med. Wissenschaften, 1883, No. 1.

squirting into the lowest part of the esophagus at the very commencement of the act of swallowing. Hence we are entitled to conclude from the delay of the murmur at the cardia that, normally, what is swallowed in each act of swallowing remains six to seven seconds just above the cardiac orifice before it reaches the stomach. With a relaxed (insufficient) or paralyzed cardiac orifice, a distinct murmur can be heard over the site of the cardia, immediately after the beginning of the act of swallowing (squirting murmur). If this "squirting murmur" be plainly heard, the later "squeezing murmur" is lacking. In this sense, the "squirting murmur" has been called first, and the "squeezing murmur" second. This terminology, however, may lead to the erroneous conception that these two murmurs necessarily belong together, that is, that they may be heard simultaneously in one and the same patient. The above discussion shows, on the contrary, that, in general, this is not true. The former shows that the action of the mylohyoid muscle and the base

Fig. 323.—Spindle-shaped dilatation of the esophagus. Right-sided dulness shortly after swallowing considerable liquid, disappearing completely on regurgitation of the fluid. Diminished vesicular breathing over the dull area. An interesting feature of this case consisted in the dislocation of the heart to the left, as shown by percussion, each time the esophagus was filled; the organ resumed its former position, somewhat too far to the left, when the esophagus was emptied. Anteriorly, nothing else abnormal could be brought out by percussing. The figure shows that spindle-shaped dilatations of the esophagus develop principally to the right side of the vertebral column. (See Corning, *Topographische Anatomie*, 1907, Fig. 212, p. 279.)

of the tongue squirts the swallowed material directly into the stomach without any obstruction, the "squeezing murmur" being absent because the cardia is not closed as it should be in normal individuals. In the latter case, that is, in the presence of a normal obstruction at the cardia, the "squirting murmur" is absent. Meltzer states, however, that in exceptional cases both murmurs may follow each other and be indistinctly heard. Either one or the other murmur can be heard in all but very few cases. Swallowing warm fluids seems to make the "squeezing murmur" more distinct. It occurs earlier in weak individuals—perhaps three to four seconds after the act of swallowing. If several swallows succeed each other rapidly, the time relation varies. Either the "squirting murmurs" become more distinct with swallowing, even where each successive act of swallowing was not heard with a single act, or we hear only a "squeezing murmur" six to seven seconds after the last act of swallowing, or, finally, we may hear nothing at all. Meltzer considers the occurrence of a distinct "squirting murmur" after a single act of

swallowing as a trustworthy sign of insufficiency of the cardiac orifice. He found it in individuals who complained of regurgitating their food with coughing, and conspicuously in patients with advanced recurring syphilis. Meltzer's swallowing murmur has thus far proved of limited clinical value. Quinke¹ pointed to a decided objection in that the swallowing murmur is differently affected by the way in which the fluid is mixed with air during the swallowing, and by the condition of fullness of the stomach. However, the occurrence of a "squirting murmur" after a single act of swallowing may, in certain cases, be considered to signify an abnormal insufficiency of the cardiac orifice, absence of "squeezing murmurs," on the other hand, may signify stenosis of this orifice.

PERCUSSION OF THE ESOPHAGUS

Percussion of the esophagus may, in rare instances, aid in the diagnosis of large "pressure diverticula" of the esophagus. If the diverticulum be filled with air, a tympanitic note can be elicited in the cervical region or at the superior thoracic aperture. If the diverticulum contain food or liquid, the note will be dulled or flat. The variations depending upon the ingestion of nourishment are especially characteristic and important for the diagnosis.

Characteristic percussion phenomena may likewise be occasionally obtained over a diffuse dilatation of the esophagus if it be distended with food. In a case observed by the author dulness was present on the right side, along the whole extent of the dorsal vertebræ. (See accompanying figure.)

ESOPHAGOSCOPY

Esophagoscopy is the inspection of the esophagus with the aid of a specially constructed instrument, a so-called esophagoscope, furnished with electric illumina-

Fig. 334.—a, Rosenheim's esophagoscope; b, its obturator.

tion. This method has recently been so perfected by the introduction of more suitable instruments that it can be carried out without any special danger or dis-

¹ Arch. f. exper. Path., vol. xxii, p. 395.

comfort to the patient. Esophagoscopy has been developed through the labors of Störck, Kussmaul, Mikulicz, Kelling, von Hacker, Killian, Starck, Rosenheim, Brünings, and others; at the present time Rosenheim's and Brünings' instruments are the most used. Rosenheim's instrument, which is analogous in principle to other endoscopic apparatus, is pictured in Fig. 334. It consists essentially of a perfectly straight tube with a circular opening at its lower end; a handle attached at right angles to its long axis; and an obturator (Fig. 334, *b*) which is removed after the introduction of the tube. The complete apparatus is furnished with several interchangeable tubes of different length and diameter, the latter measurements varying from 11.5 to 13 mm., with sponge-holders for wiping the interior of the tube, forceps for extracting foreign bodies, and sounds. Casper's panlectroscope attached to the handle (Fig. 334, *a*) supplies the light. It consists of a small incandescent lamp whose light is directed into the tube in parallel rays by means of a plane mirror. This attachment has the disadvantage of obstructing one-half of the lumen of the tube, as is plainly seen in the accompanying illustration; introduction of instruments for cleansing the field of vision or for operative purposes is thus difficult. Accordingly, Starck recommends Kirstein's electric head-lamp as a more suitable source of light; one hand of the operator controls the esophagoscope, while the other is employed in manipulating the instruments introduced through the tube. Earlier operators made use of laryngeal reflectors, which were attached to the forehead of the examiner, while still others made use of a small electric lamp attached to the lower opening of the tube, as in Strauss's rectoscope (Fig. 211, p. 503). The laryngeal mirror, however, does not furnish a sufficient amount of illumination, while the introduction of an electric lamp into the tube obstructs too much space within its lumen. Before introducing the instrument, the pharynx, especially the lateral pharyngeal walls, the region of the cricoid cartilage and of the pyriform sinuses should be anesthetized with a 10 per cent. solution of cocain. Starck recommends a 3 per cent. solution of β -eucain. In less sensitive patients who have been repeatedly examined it is possible to introduce the esophagoscope without preliminary cocainization. Rosenheim recommends the patient to lie on his back upon the examination table, with his head hanging down directly backward; but von Hacker introduces the instrument with the patient in the sitting posture on the middle of the operating table, with bared throat and thorax, and places him on his back after introduction. The physician stands on a stool to the right of the patient; behind the latter stands an assistant ready to support and move the patient's head. The operator presses the back of the tongue as far forward as possible with his left index-finger; with his right hand he introduces the instrument, previously lubricated with vaselin, and with its obturator in place, into the entrance of the esophagus, following the right pharyngeal wall and pushing aside the right corner of the mouth. During this maneuver the patient holds his head as erect as possible; but then his head is slowly bent backward while the instrument is pushed onward. After the instrument has been introduced, the patient is slowly lowered to a horizontal position, with his head hanging down backward off the operating table. The obturator is then removed, the illuminating apparatus is brought into action, and the whole esophagus examined, the tube being carefully moved up and down. Kraus also introduces the esophagoscope in the sitting posture, unless the patient be troubled with excessive secretion of mucus; he, however, places the patient upon a low footstool. If, however, there be difficulty in wiping away the mucus, he makes use of von Hacker's method, afterward bringing the patient in the horizontal position, with his head hanging over the edge of the table. This procedure allows the mucus to escape out of the mouth by itself.

Recently esophagoscopy has been further perfected and simplified, as far as illumination is concerned, by the introduction of Brünings' esophagobronchoscope (Figs. 335 and 336.) With his instrument both bronchoscopy and direct laryngoscopy may also be carried out. (See Autoscopy or Orthoscopy of the Larynx, p. 901.) The essential modification consists in the substitution of two telescoping tubes for

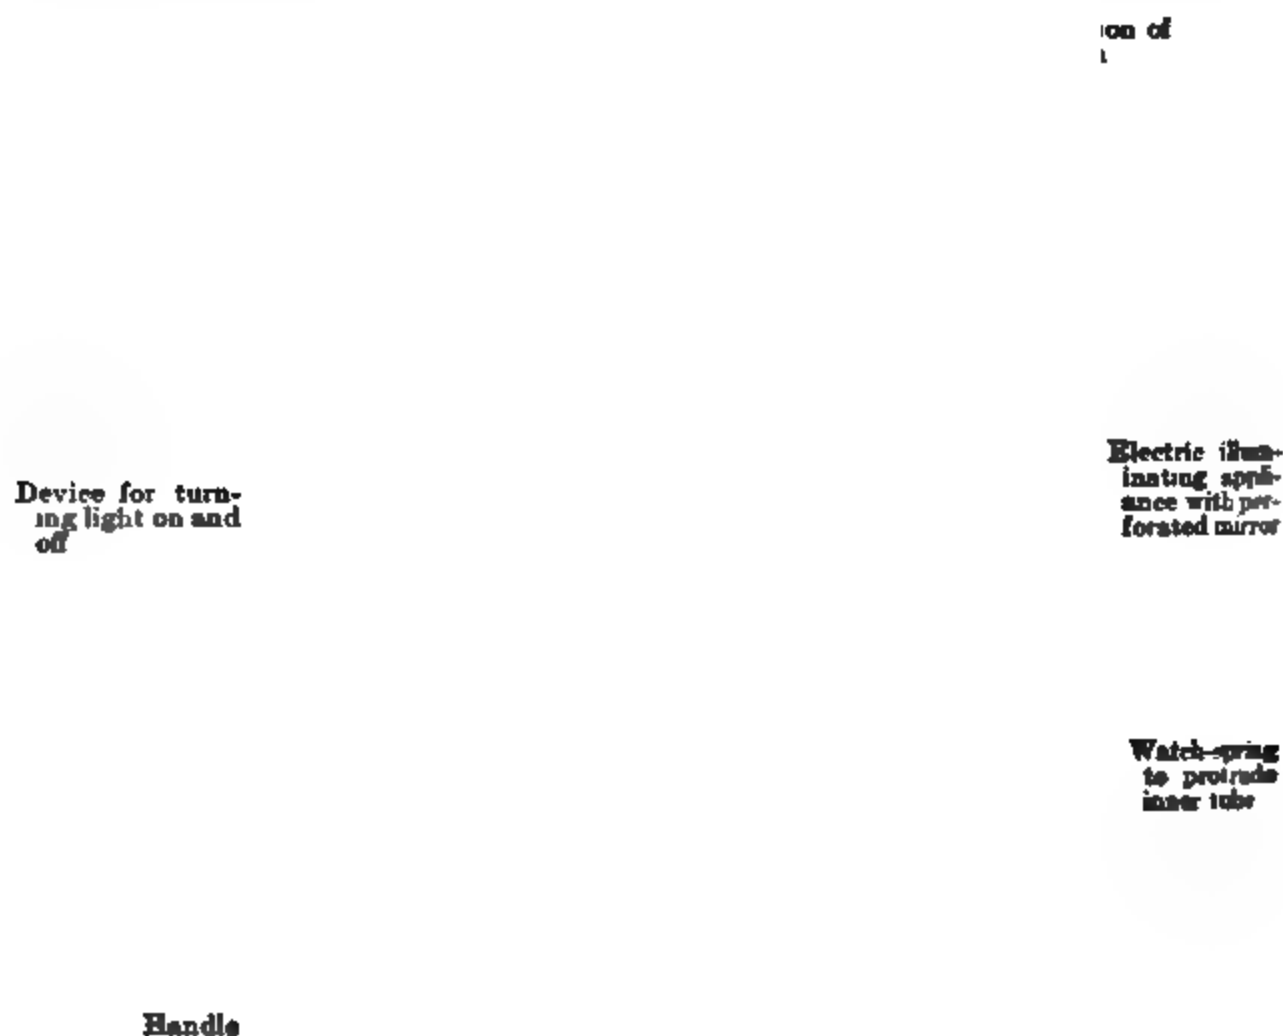

Fig. 335.—Spatula tube and movable tube of Brünings' esophagobronchoscope.

the one tube of the esophagoscope, one of them being called the spatula tube and the second the movable tube (Fig. 335, *a* and *b*). The latter tube fits accurately into the former and can be pushed forward in its lumen by means of a weighted watch-spring *c*. This arrangement greatly simplifies the necessary manipulations, because it allows one to lengthen the esophagoscope after the introduction of the instrument; in addition, the tube does not stick out from the patient's mouth in such an inconvenient manner as is the case with the older instrument, when the upper portions of the esophagus are examined. The *spatula* is provided with a centimeter scale which is measured from the end of the tube, though the markings begin at a distance of 10 cm. from that end (Fig. 335). A similar scale, seen in the

Esophagoscope tube, represented broken off at end
Fig. 336.—Brünings' bronchoesophagoscope.

picture, is marked upon the watch-spring attached to the inner tube of the instrument. These scales enable the observer to estimate the depth to which the inner tube is introduced, as well as the total length of the tube at any stage of the examination. The introduction of the *spatula* is facilitated by employing an obturator constructed out of the flexible material used in bougies; it is made pointed at one end and projects beyond the end of the tube. A further modification, useful if the obturator be not used, consists in the slightly curved, bill-like lower end of the tube designed to overcome the angle between the mouth and the esophagus (Fig. 335). Brünings' instrument is provided with a perfected illuminating apparatus (Fig. 336), light being derived from a small electric lamp the rays of which are made parallel

by passing through a lens. This light falls on a plane mirror which makes an angle of 45 degrees with the long axis of the tube, thus throwing the light into the interior parallel to this axis; the observer looks directly into the lumen of the tube through a central opening in the mirror, as in the ophthalmoscope. This illuminating apparatus, which is firmly attached to the tube of the esophagoscope, can be rotated to one side, thus making the tube more accessible. The incandescent lamp is provided with a specially constructed filament, the light being concentrated upon a single point upon which the movable illuminating lens can be exactly focused. This arrangement results in very intense illumination. Brünings' apparatus is, in addition, provided with various accessory parts, such as a pump for removing the saliva, sponge-holders, forceps for foreign bodies, etc. For bronchoscopy the makers supply smaller tubes, which can be attached to the handle containing the illuminating apparatus (Valentin's salpingoscopy, etc.). The instrument is sold by M. Schärer in Bern.

The rules given for esophagoscopy in general apply to the use of Brünings' instrument. For details the book of instructions accompanying the instrument may be consulted, as well as Brünings' work, entitled *Die Technik der Bronchoskopie und Oesophagoskopie*, Bergmann, Wiesbaden, 1908. Starck's monograph (Würzburg, A. Stuber's Verlag, 1905) may also be consulted, for it contains a historic review of the development of this method of examination.

So far as the pictures obtained by the esophagoscope are concerned, the following data will suffice here. The cervical portion of the esophagus appears through the instrument as a closed tube, because of the pressure of surrounding parts; its thoracic portion, on the other hand, appears wide open, because of the negative pressure within the thorax, so that the observer is able to see a considerable portion of the organ beyond the end of the esophagoscopic tube. The color of the normal esophageal mucous membrane is pale red. Esophagoscopy allows one to observe pathologic changes very easily, such as catarrhal and ulcerative processes, peptic ulcer of the esophagus, ulcers caused by foreign bodies, scars due to syphilitic lesions and to burns by caustics, carcinomata, etc. The latter may be observed in their early stages, while examination with sounds demonstrates them only when far advanced. A purely spastic esophageal stenosis can be demonstrated perfectly by this method, the esophagoscopic picture in such a case showing no anatomic changes in the walls of the esophagus whatever. In cases of diffuse dilatation of the esophagus the observer finds that the view into the lower portions of the organ, which normally is wide open, is obstructed by folds of mucous membrane encroaching upon the lumen, but which are easily pushed aside. The mouth of Zenker's pharyngo-esophageal pressure diverticulum is difficult to see by this method, because it is found at the very entrance of the esophagus, and is, therefore, hidden by the instrument as soon as it is introduced to the depth of a few centimeters. For special findings the reader is referred to the consideration of the various affections of the esophagus.

MEASUREMENT OF PRESSURE IN THE ESOPHAGUS

Mikulicz¹ has furnished interesting and important information in reference to the measurement of the intraesophageal pressure, which indicates both the motor power of the esophageal musculature and the tonus of the cardia. It is necessary to have a mercury manometer with an index of 100 mm.; the pocket mercury manometer described upon p. 165 may be employed. A thin, soft-rubber esophageal tube (see p. 439), of sufficient resistance to overcome lateral compression, is introduced into the esophagus until its open end is at the level of the manubrium. Before the introduction of the tube its outer end is clamped, and the clamp is not removed until the tube has been connected with the manometer. When the clamp is removed, the mercury usually falls, indicating that the end of the tube is within the thoracic portion of the esophagus. When the patient swallows, the mercury rises, and this elevation, according to Mikulicz, should amount to about 10 mm. A diminution of this pressure may be due either to atony of the esophageal musculature or to a diminished tonus of the cardia, which latter, by relaxing, would prevent the production of a greater pressure. The tonus of the cardia is now estimated by determining the pressure at which fluids flow into the stomach. For this purpose a T-tube is inserted between the esophageal tube and the manometer, and its horizontal limb connected with a funnel by rubber tubing. Fluid at body temperature is then poured into the funnel, and the pressure is read from the manometer at the

¹ Deut. med. Woch., 1904, Nos. 1 and 2.

moment the fluid commences to run into the stomach. In carrying out the latter manipulation the lower end of the esophageal tube must be pushed down to just above the cardia, otherwise the hydrostatic pressure of the column of fluid collecting between the opening in the end of the tube and the cardia would be lost. Since the tube and its connections with the manometer are filled with fluid, care must also be taken to bring the zero-point of the manometer to the level of the cardia, since it is at this point that we wish to determine the pressure. According to Mikulicz the initial pressure at which lukewarm, indifferent fluids flow into the stomach varies between 2 and 17 mm. of mercury. The resistance of the cardia is shown by the values obtained by this method. Abnormally low or high pressures are indicative of corresponding variations in the tonus of the cardia. With due regard to the results obtained by this method, we may determine whether a low or a high pressure during deglutition is due simply to a diminished or an increased resistance of the cardia or to abnormal conditions of the esophageal musculature. After the introduction of the fluid, it is well for the patient to repeat the act of deglutition, when the pressure should be measured again.

This procedure may also be employed for the estimation of the capacity of the esophagus, which is of importance for the diagnosis of diffuse esophageal dilatation, a subject about which so much has recently been written. The greater the amount of fluid which can be poured into the esophagus before any of it escapes into the stomach, the greater is the esophageal capacity. If such a diffuse esophageal dilatation be due to cardiospasm, as is usually the case, it will be found not only that a large quantity of fluid may be introduced into the esophagus before any of it flows into the stomach, as indicated by a sudden fall of the mercury, but that the fluid does not enter the stomach until it is acted upon by an abnormally high pressure.

THE PERMEABILITY OF THE CARDIAC ORIFICE OF THE STOMACH FROM THE STOMACH TOWARD THE ESOPHAGUS

For practical purposes it is usual to determine the permeability of the cardiac orifice in the direction from the esophagus toward the stomach. Meltzer, however, has pointed out the importance of determining the permeability of this orifice in the opposite direction, from the stomach toward the esophagus. He first questions the patient as to his ability or inability to vomit or to retch. Tickling of the pharynx without producing vomiting can sometimes be demonstrated. This he determines if the answers to his questions suggest its advisability. Further data are obtained by attempting to fill the stomach with air through a stomach-tube. Normally, the air escapes back through the tube after a moderate degree of distention has been reached; but in cases of spastic stenosis of the cardiac orifice the air remains in the stomach, to the discomfort of the patient, though a high degree of pressure has been reached. On the other hand, in insufficiency of this orifice or in carcinoma at the cardia interfering with its closure, it is quite impossible to distend the stomach to any noticeable extent, for the air introduced through the tube escapes almost immediately. These observations, if critically applied, are valuable in the determination of functional disturbances, such as form the foundation for abnormal eructation and vomiting, as well as for that curious regurgitation phenomenon termed merycism or rumination. In his study of the mechanism of eructation Meltzer has found that in this act, just as in vomiting, the cardiac orifice is opened with the help of the abdominal muscles and the diaphragm, escape of air occurring when this has taken place; after each act of eructation the esophagus contracts in a peristaltic wave, from above downward, without the assistance of the constrictors of the pharynx. Meltzer has found further that there may occur eructation of air from the esophagus proper and not from the stomach; this is differentiated from eructations originating in the stomach by the absence of a murmur on auscultating the epigastric region.

RÖNTGENOLOGIC EXAMINATION OF THE ESOPHAGUS

Both fluoroscopic examination and x-ray photographs of the esophagus may be used in diagnosis. The heart shadow interferes with the recognition of the esophagus if the latter be viewed in the sagittal direction; it is, therefore, advisable to direct the rays from the left side toward the back and from the right side toward the front. This position hides the heart shadow almost completely, both on the screen and in photographs, because of the great distance of the heart from the screen or the plate; but the esophagus becomes as plainly visible as if the heart had been completely removed. If the patient swallow some bismuth mixture, made

by thoroughly mixing 10 to 20 gm. of bismuth subnitrate or, better, the less toxic bismuth carbonate with potato porridge, the portion of the esophagus which contains this substance appears as a shadow in the fluoroscope or on the radiograph. If stenosis exist, the lower end or the narrowed portion of the bismuth shadow closely corresponds to it, and any dilatation above the obstruction may also be directly visible. Diverticula and diffuse dilatations of the esophagus exhibit an especially clear picture in this method of examination. Still another device, more suitable for fluoroscopy than for x-ray photography, consists in the introduction of a semi-flexible tube to the tip of which is tied an empty rubber balloon; this balloon is wound up spirally about the sound before the introduction of the latter, and is well lubricated. The balloon is then gradually inflated by means of a rubber bulb attached to the external end of the tube, and appears as a bright space in the fluoroscopic picture. By varying the degree of inflation of the balloon and by moving it up and down it is possible, so to speak, optically to palpate the esophagus. This procedure is especially suitable for the recognition of diffuse dilatations. To facilitate the recognition of the topography of the esophagus the blind end of the balloon may be filled with a dessertspoonful of bismuth subnitrate before attaching it to the tube; in such a case it appears as a dark shadow in the fluoroscopic picture below the bright space which represents the rest of the balloon. The same result may be obtained by filling the balloon, after its introduction, with a watery suspension of bismuth. The choice of methods depends upon the character of the "x-ray" tubes used, now one, now the other, giving the best results. It is also possible, of course, to combine both principles of examination, that is, the production of the light space and of the shadow, by first filling the balloon with air and then with bismuth suspension. In diffuse dilatations useful observations may be obtained occasionally by fluoroscopy after introducing a tube filled with shot or quicksilver. If, as is usually the case in this condition, an obstruction be present at the cardia, and if a marked diffuse dilatation of the esophagus have resulted, the tube is to be seen curved upon itself in the dilated portion, the size and shape of the curve allowing judgment upon the caliber of the dilatation. A semisolid sound provided with a wire obturator may be used for this purpose.

SPECIAL FINDINGS IN THE MOST IMPORTANT AFFECTIONS OF THE ESOPHAGUS

Carcinomata of the Esophagus.—The most important procedure in the diagnosis of carcinoma of the esophagus is examination with the sound, by means of which an obstruction is usually discovered if thick, olive-pointed bougies be used, and the diameter of the stenosed portion be determined by passing sounds of various calibers. If the obstructed portion be permeable, its vertical extent is determined by finding the difference between the position of the obstruction in passing the sound and in withdrawing it. In the great majority of cases esophageal carcinomata are found at the level of the tracheal bifurcation, that is, at a distance of 23 to 25 cm. [9 to 10 in.—ED.] from the incisor teeth. The obstruction due to the presence of carcinomata may be found to vary in degree on different examinations, as a result of the varying spastic conditions induced in the esophagus and the different degrees of destruction in the morbid tissue. If the nature of the obstruction be in doubt, a clue may be obtained by examining with hard or moderately soft tubes possessing lateral fenestrations (p. 445 et seq.); on withdrawing the tube, particles of cancer tissue are frequently found in the fenestrations. As a rule, esophagoscopy immediately reveals the carcinomatous nature of the obstruction. This is the only method which allows an early diagnosis of this condition by the demonstration of a characteristic cancerous growth, for occasionally, in the early stages of the disease, no obstruction is perceived on passing sounds, though difficulty in swallowing may be present. An early diagnosis may yet become of more practical importance if the negative or the positive pneumatic pressure methods render them more accessible to operation. On the other hand, if the cancerous growth be still covered by intact mucous membrane, the tumor may not be apparent on esophagoscopy examination, because above it the tube of the instrument may be obstructed by the swelling due to submucous infiltration of the tissue. The act of swallowing in patients suffering from esophageal carcinoma is characteristic of the affection. Just as in all true stenoses of the esophagus, this act is performed very carefully after thorough mastication, because the patients have learned that swallowing is possible only when such care is exercised, while hasty swallowing usually leads to an immediate regurgitation of the food. The diagnostic significance of metastases in the regional lymph-nodes, in the lungs,

and the mediastinum, as well as the significance of certain paralytic phenomena, such as the paralysis of the recurrent laryngeal nerve or of the papillary fibers of the sympathetic, together with the study of perforations of cancer in the neighboring structures, will be considered in the sections on Special Diagnosis.

Diverticula of the Esophagus.—As is well known, only the saccular pressure diverticula are of clinical importance, so far as difficulty in swallowing is concerned. Two varieties of these diverticula are recognized—the high-seated diverticula, taking their origin at the level of the cricoid cartilage, and the deep-seated pressure diverticula, found in the midthoracic portion of the esophagus. The first-named structures are also called Zenker's or esophagopharyngeal diverticula, and probably depend for their origin upon congenital defects of the musculature of the esophagus and pharynx. The peculiar findings obtained in passing sounds into the esophagus form the principal factors in the demonstration of saccular diverticula. On one occasion, the obstruction which is caused simply by the pressure exercised upon the gullet by the filled sac may be overcome in passing the sound, and the latter may reach the stomach; on another, this proves to be impossible, different results being obtained with different degree, of distention of the sacs. If the passage of the sound prove possible, either an elastic obstruction, which is easily overcome, is encountered or no obstruction at all is felt, depending upon the condition of the sac at the time. Of course, if the sound enter the sac, the obstruction proves to be impermeable. These variable findings may lead to the suspicion that a diverticulum exists, but a positive diagnosis cannot be made from them alone because, as we have seen, obstruction due to carcinoma may lead to similar conditions. Differential diagnosis between these two conditions is made from the results of examination by means of a diverticulum sound (see p. 882), which usually shows that the tip of the sound passes the obstruction or is arrested, according to the direction given to it. Pharyngo-esophageal or Zenker's diverticula are usually directed backward from the esophagus; the deep-seated diverticula, originating on the level of the tracheal bifurcation, on the other hand, are situated in front of the gullet. The diverticulum sound must, therefore, be directed according to these usual situations of the diverticula; in order to overcome the obstruction in the former the tip must be directed forward, and in the latter backward. The fact that large quantities of decomposing food may be obtained if the sound enter the diverticulum is another characteristic of this condition. (See p. 431 for the differences between gastric contents and the contents of diverticula.) The act of swallowing is performed just as deliberately as with carcinoma, because swallowing, is often possible when done in this manner: whereas, if rapid, the sac is filled and makes further descent of food impossible. Patients suffering from high-seated Zenker's diverticula often help themselves out in a very characteristic manner by compressing the mass which, in swallowing, forms upon one side of the throat. Often they make various peculiar movements of the head in order to assist swallowing. In the presence of a diverticulum, regurgitation is usually much more abundant and occurs later than in carcinoma; in the latter regurgitation often follows almost immediately upon the act of swallowing, because no marked dilatation is present above the obstruction. A visible and palpable prominence on one side of the neck, forming immediately after the act of swallowing, is characteristic of a high-seated Zenker's diverticulum; this swelling is tympanic when filled with air, and gives a dull note on percussion when filled with fluid or solid material. Occasionally the diverticulum is large enough to reach into the thorax; and then these variations in percussion may then be observed in the upper portions of the thorax, usually anteriorly, because Zenker's diverticula, although originating from the posterior surface of the esophagus, increase and spread forward in accommodating themselves to the free space in the thorax. The dull note over these diverticula usually disappears and is replaced by a tympany after the patient has vomited the fluid contents of the sac. Deep-seated diverticula furnish similar dull areas to percussion, which are to be looked for on the posterior surface of the thorax, in the neighborhood of the spinal column.

Diffuse (Spindle-shaped) Dilatation of the Esophagus.—This affection is rare, but important, from the standpoint of diagnosis, being usually dependent upon a spastic condition of the cardiac orifice. The first sign it manifests is the existence of an elastic obstruction (cardiospasm) at the level of the cardia, which is readily overcome if the examiner employ a fairly soft tube and exercise a little patience. It is very characteristic of this affection that before the obstruction is overcome a longer portion of the sound can be pushed down than would correspond to the position of the cardia—that is, more than 40 cm. [16 in.—Ed.] as measured from the incisor teeth. This can evidently be accounted for by the deviation of the soft tube toward one side of the dilated esophagus. If the force with which the

sound is pushed downward be diminished before the obstruction is overcome the sound appears to spring back a few centimeters. After the sound has penetrated the cardiac orifice, the sensation of an elastic constriction about it is communicated to the hand, although after this is overcome, the sound can be pushed on further with only a certain amount of difficulty. Large quantities of food-remains are frequently obtained through the tube when it enters the esophagus. These remains may be recognized as coming from the esophagus by their alkaline or at most faintly acid reaction, or at least by the failure to give a reaction for free hydrochloric acid with Congo red. (See p. 449.) If the tube have passed the cardia and the stomach still contain food ingested not too long before the examination, gastric contents may be expressed, which can be easily recognized by the positive reaction for free hydrochloric acid with Congo red. If, however, the stomach be found empty or the material obtained do not contain free hydrochloric acid, the last-mentioned evidence of the fact that the cardiac obstruction has been overcome cannot be obtained. After a certain experience, however, the other signs cited above are quite sufficient to decide whether the tube is still in the esophagus or in the stomach. In addition, other tests may be mentioned. If liquid be introduced and the tube withdrawn, the patient can generally discriminate between the sensation of discomfort and oppression which accompanies overdistention of the esophagus from that of a filled stomach. The patient cannot voluntarily regurgitate the fluid introduced into the stomach, although he usually can the contents of a dilated esophagus and with ease. In cases of a diffuse dilatation of the esophagus it is possible to bend the tip of a diverticulum sound strongly at any level without meeting any well-marked resistance and without causing the patient any pain. As contrasted with the condition in the common strictures of the esophagus the type of swallowing in patients suffering from diffuse dilatation of the esophagus is quite characteristic. They usually swallow very rapidly and in large gulps. They hastily pour down large quantities of fluid, because the marked increase of pressure thus produced in the esophagus carries down at least a portion of the swallowed material into the stomach. The patient practically uses the last portions swallowed as a piston to push down the lower strata of the food into the stomach. Röntgenologic examination plays an important rôle in and has materially simplified the diagnosis of these diffuse dilatations. The technical devices used in this method of diagnosis, such as the use of a sound filled with mercury or with lead, the introduction into the esophagus of a balloon, which is then inflated with air or filled with a suspension of bismuth, the introduction of a bismuth mixture into the dilated esophagus itself, etc., have been described on p. 892. All these methods furnish good results, the best of them being those obtained by photographing the esophagus after the introduction of the bismuth mixture from the right side toward the front or from the left side toward the back, with the plate in front of and the tube behind the patient. The measurement of the intraesophageal pressure (see p. 891) may sometimes be used in the diagnosis. (For the views of the diffuse dilatations of the esophagus obtained by the esophagoscope see p. 891.) Auscultation of the thoracic portions of the esophagus (Hamburger's swallowing murmurs, see p. 881) gives almost normal results in the presence of a diffuse dilatation. In the majority of cases the affection is due to the presence of a cardiospasm, and, therefore, in the auscultation of the epigastrium the squirting murmur of Kronecker and Meltzer, as well as the squeezing murmur, are often either entirely absent or very indistinct; frequently they are very much delayed. (See p. 882.) In one case of a diffuse dilatation of the esophagus the author obtained very characteristic percussion findings. When the patient filled his esophagus by drinking water or by swallowing food, there appeared a characteristic zone of diminished resonance, narrower in its upper portions, along the right side of the spinal column. Evidently this zone of diminished resonance was caused by the overfilled esophagus compressing the neighboring part of the lung; the auscultation phenomena in the lung were not in any way characteristic, but the apex of the heart was displaced toward the left, even when the esophagus was empty, probably because of the continued pressure upon it. As soon as the patient regurgitated the material that filled his esophagus, the zone of dulness in the chest disappeared and the heart was less displaced. The author does not know whether similar observations have been made in any other case.

Mention must also be made of Rumpel's experiment for differentiating spindle-shaped dilatations of the esophagus from deep-seated diverticula. Rumpel introduces an elastic tube which, in addition to the end opening, has a number of lateral perforations in its lower half. When it is certain that the tip of this tube is in the stomach, a second and smaller tube is introduced into the esophagus alongside of the first one until a resistance is encountered. Water is then poured into the esoph-

agus through the latter. If a spindle-shaped dilatation be present, the water immediately flows into the stomach through the lateral perforations in the tube first introduced, so that none of it may be recovered through a second tube. If there be a diverticulum, however, at least a portion of the water introduced may sometimes be siphoned out through the second tube. A number of difficulties are encountered in carrying out this experiment. In the first place, it is not always easy to introduce the first tube or to determine that it extends into the stomach, since it may become bent upon itself either in a spindle-shaped dilatation or in a diverticulum. If a diverticulum be present, moreover, it is not such a simple matter to introduce the second tube into it. The first difficulty may be overcome by performing the experiment upon a full stomach, and introducing the first tube so far that all the perforations are presumably in the stomach; the gastric contents are then siphoned out, indicating that the tube has really passed the cardia. The tube is then withdrawn until only the open end remains in the stomach, and the experiment is then carried out in the usual manner. To diagnose a diverticulum, it is necessary not only to introduce a tube into it, but also to recover through this tube a part or all of the fluid introduced. A diverticulum sound may be substituted in order to reach the diverticulum more readily.

In view of these difficulties, and the further one of introducing a second tube alongside of one already in the esophagus, the author adds a procedure suggested by Richartz¹ for the differentiation of spindle-shaped dilatations of the esophagus from deep-placed esophageal diverticula. The dilated esophagus is well irrigated, so that all particles of food are removed. A tube similar to that used by Rumpel, with an end opening and numerous lateral perforations, is then introduced almost to the cardia. This tube is connected with a funnel. The esophagus is then thoroughly irrigated with a solution of methylene-blue, the fluid being introduced and withdrawn a number of times, so as to be sure that a diverticulum, if present, is filled with the methylene-blue solution. If the patient strain slightly, some of the solution will be forced back into the funnel, proving that the tip of the tube is within the esophagus. The tube is now slowly pushed down into the cardia, allowed to remain there a short time, and then drawn back to its former position. In pushing the tube downward, the fluid in the esophagus runs into the stomach. Clear water is then introduced into the esophagus through the funnel and recovered by siphonage, and this procedure is repeated several times. If a fusiform dilatation be present, the water returns colorless; whereas if there be a diverticulum, the returning water will be intensely stained from the retained methylene-blue solution.

Under certain circumstances, Rumpel's experiment may be simplified by introducing the perforated tube just to the cardia, filling the esophagus with water, and then pushing the tube downward into the stomach, when the water will flow into the stomach, provided that it has not been caught by a diverticulum. The tube is then withdrawn until the end is just above the cardia. If the patient, by straining slightly, is now able to empty a portion of the fluid introduced, it necessarily follows that a diverticulum must be present.

These and similar experiments may be carried out with variations dependent upon the individual case.

The introduction of *x*-rays has, however, made these procedures quite superfluous; indeed, Röntgenologic examination has taken their place almost completely, because of the discomfort caused by them to the patient and the frequently uncertain results furnished by their use.

APPENDIX.—THE DEMONSTRATION OF ENLARGED TRACHEAL AND BRONCHIAL LYMPH-NODES

Enlarged tracheal or bronchial lymph-nodes cannot, as a rule, be demonstrated by percussion, and even Röntgenologic examination shows them only when they are greatly hypertrophied. E. Neisser² has, therefore, proposed to test the sensitiveness to pressure of such tuberculous glands by means of a sound introduced into the esophagus and then distended. The nodes that come within the possible field of this examination are, in Sukienrikow's terminology,³ the inferior and the left tracheobronchial lymph-nodes, that is, the group situated in the obtuse angle formed by the trachea and the left bronchus, and those found between the two main bronchi. These two groups are immediately adjacent to the esophagus, while

¹ Deut. med. Woch., 1904, No. 21.

² Neisser, Deut. Arch. f. klin. Med., 1905, vol. lxxxvi, p. 28.

³ Berlin. klin. Woch., 1903, vol. xvi.

the right tracheobronchial group of glands, as well as the bronchopulmonary group situated in the hilum of the lung itself, cannot be approached from the esophagus. E. Neisser's procedure in testing the sensitiveness of these nodes consists in the introduction of a soft narrow sound to the tip of which a finger-cot has been tied. By means of a Politzer bag connected with the external end of the sound tube the finger-cot is then inflated at the level of the bifurcation. In examining different levels by this means it is advisable to allow the finger-cot to collapse before changing the position of the tube, and then reinflate it at another level. The author believes that the same results may be obtained by using Trousseau's olive-pointed sounds of appropriate caliber. The dilatation sound described on p. 882 (Fig. 332) may, however, be selected to carry out Neisser's procedure; the only change necessary is to arm the tip of the sound with a thin instead of the usual thick finger-cot. With this modification the amount of pressure employed can be estimated more easily, and, in addition, none is lost in transmission, because of the less resistance of the thin-walled covering.

LARYNGOSCOPY AND TRACHEOSCOPY; AUTOSCOPY OF THE LARYNX AND TRACHEA; BRONCHOSCOPY

EXAMINATION WITH THE AID OF A MIRROR

Since the invention of the laryngeal mirror by Garcia, Türk, and Czermak, mirror examination has played the most important part in the diagnosis of diseases of the larynx and trachea.

The principle of this method of examination is as follows: A reflector (a perforated, slightly concave mirror), which is ordinarily fastened to the examiner's head so that the central opening is opposite one of his eyes, collects the rays of light from the source of illumination (Argand burner, Welsbach light, electric light, or student lamp) and converges them into the back of the patient's throat upon a small mirror attached to a handle at an angle of about 45 degrees. The reflector and the laryngeal mirror are so arranged as to throw an intense illumination into the larynx, and at the same time reflect a virtual image of the illuminated parts to the examiner's eye.

In the ordinary position the base of the tongue hides the opening of the larynx, so that it is necessary for the patient to protrude his tongue as far as possible, while the examiner at the same time holds it firmly in position with a napkin or towel. Fig. 337 and the following pages explain the methods of application of the laryngoscope. Fig. 338 shows the path of the rays of light in laryngoscopy and tracheoscopy. The latter figure clearly illustrates the fact that to see the larynx plainly the laryngeal mirror must be held more vertically and introduced further backward; whereas, to observe the trachea, it must be held more horizontally and farther forward. The lower the handle is depressed, the more the parts which lie still farther backward come into the field of vision. The following sequence in the appearance of the parts in the field of vision is accomplished by gradually depressing the handle of the mirror: epiglottis and base of the tongue, anterior commissure of the vocal cords and anterior laryngeal wall, anterior tracheal wall, bifurcation, posterior tracheal wall, posterior laryngeal wall, and arytenoid cartilages. Fig. 339, copied from Heitzmann, represents a normal laryngeal picture.

A Few Details for the Practical Employment of Laryngoscopy.—The source of light and the heads of the examiner and patient should be practically at the same level. The laryngeal mirror should be heated over the lamp immediately before each introduction, to prevent its being diminished by condensed moisture.¹ In warming the mirror the glass slide should be held at some distance above the flame, and the degree of warmth tested by touching the back of the mirror to the examiner's hand. Not only is it necessary for the examiner to hold the tongue firmly as well as carefully, but it should be actively protruded by the patient, as otherwise a little pain and a reflex bulging of the posterior part may be produced, and thus render the examination difficult. To prevent gagging the examiner should carefully avoid touching

Fig. 337.—Technic of laryngoscopy.

with the mirror the pharynx, and especially the posterior pharyngeal wall and the base of the tongue. Touching the uvula ordinarily causes less trouble, and, as it so often drops down in front of the mirror, one can sometimes simplify the examination by supporting and pressing it upward and backward with the back of the mirror. The examination is almost always facilitated by convincing the patient that it is not in any way painful, and that, even though at the beginning the procedure may produce gagging, quiet and patience will always accomplish the result. The patient should always inhale quietly and regularly, and should say "Ah" with expiration, thus elevating the epiglottis, and so permit the examination of the interior of the larynx. If the epiglottis be depressed enough to obstruct the view, saying "ee" will usually elevate it sufficiently. It is rarely necessary to employ an

¹ The same purpose can be accomplished by coating the surface of the mirror with a very thin invisible layer of soap [or with a solution of lysol.—Ed.].

instrument which has been constructed for the purpose of elevating the epiglottis, nor to cocaine the pharynx, provided one takes the time and has the patience to get the patient somewhat accustomed to the examination. If cocaine is to be employed, the pharynx should be painted with 5 per cent. solution of cocaine hydrochlorid, and the patient should be instructed to spit out the solution immediately after its application, in order to prevent intoxication. In examining the larynx we should pay particular attention to the mobility of the parts, especially the vocal

Fig. 338.—Diagrammatic representation of direction of rays of light in laryngoscopy and tracheoscopy (sagittal section of head and neck): a, Position of mirror for laryngoscopy; b, position of mirror for tracheoscopy.

cords, to their color, to accidental alterations in the surface (swelling, ulcerations, coating with mucus, etc.). It is impossible to go into a detailed description of the results of examination, and so the author will limit himself to appending the accompanying illustrations, which represent a few of the commonest and most important findings.

The same principles and rules apply to **tracheoscopy**. The patient should, however, sit considerably higher than the physician, so that the mirror can be held more horizontally and looked up into from below. Further, the patient should hold his trunk and neck quite

straight, and at the same time bend his head forward at the atlanto-occipital joint (chin against the neck). This position brings the axis of the pharynx into a more favorable position for tracheoscopy. The trachea cannot be observed well in all individuals, but in many we can get a view as far as the bifurcation without any special difficulty. In such cases all sorts of tracheal stenoses can be examined and recognized. Fig. 347 represents the normal tracheoscopic picture with the anterior

tracheal wall. Fig. 348 represents the same with the posterior tracheal wall (a different position of the mirror). Both show the bifurcation of the trachea.

Inferior tracheoscopy or *laryngoscopy* means the examination of the trachea or larynx from a tracheotomy wound. For this purpose we

employ a so-called "subglottic mirror," which is constructed in quite the same fashion as the laryngeal mirror, except that it is much smaller (diameter of 7 to 10 mm.). This is introduced through the tracheal wound, and the illumination is thrown in from the reflector in the same way as described above. Its principal use is to determine the causes which prevent the withdrawal of the cannula in croup operations.

DIRECT EXAMINATION OF THE LARYNX, TRACHEA, AND BRONCHI

(Autoscopy; Orthoscopy; Direct Laryngoscopy, and Tracheoscopy)

A. Kirstein¹ has described a method of examining the larynx and trachea without employing a mirror. The base of the tongue is drawn forward with the aid of a spatula-shaped instrument, and the larynx and trachea are then examined directly. Kirstein described this method under a rather unfortunate term—"autoscopy"

¹Therap. Monatshefte, 1895, vol. ix, p. 361, *ibid.*, 1896, p. 370; Encyklop. Jahrbücher, 1896, vol. vi, p. 30.

of the larynx and trachea. It would seem more correct to name the procedure "orthoscopy of the larynx and trachea," or "direct laryngoscopy and direct tracheoscopy" (as opposed to indirect or mirror laryngoscopy and tracheoscopy). Kirstein employs for direct laryngoscopy the instrument pictured in Fig. 349, the so-called "autoscope"; but for most cases he has more recently substituted a simpler instrument, which is nothing but a tongue depressor of a particular shape (Fig. 351). The original "autoscope" is now recommended by Kirstein only for performing autoscopic operations for demonstration and for examining children.

The "autoscope" (Fig. 349, 1) consists of a grooved metallic spatula (*S*), about 12 cm. long and about 3 cm. wide. The groove varies from 1 to 2.5 cm. in depth. It is removable and is attached at a right angle to the handle (*G*), and well rounded off to prevent injury. The anterior end (*d*) of the spatula is quite sharply bent downward; and attached to its end, next to the handle, is an electric lighting apparatus (not shown in the figure), so arranged that a cone of rays is transmitted by means of a prism along the groove exactly in its long axis. A contact contrivance for the electric light is shown in the figure. The part *r*, which is movable, forms a kind of a roof or sheath to the grooved spatula, and so prevents the upper lip or the mustache from obstructing the view. The application of the instrument can be readily understood by studying Fig. 350.

Fig. 349.—Kirstein's autoscope: 1, Ordinary spatula; 2, intralaryngeal spatula.

The instrument is grasped by the handle and inserted so that the tip of the grooved spatula lies between the base of the tongue and the epiglottis. The base of the tongue is then hooked downward and forward by raising the handle of the instrument a little, and the epiglottis is slightly raised by pulling upon the median glosso-epiglottic ligament. Pressure upon the teeth must be avoided. If the epiglottis obscure the view into the larynx, cocaine may be applied and the instrument introduced directly behind the epiglottis. For this purpose a differently shaped spatula (Fig. 349, 2) is employed.

After the instrument is properly introduced, the examiner looks down between the upper teeth and the grooved spatula with the aid of the electric illuminator. Fig. 350 illustrates the position of the patient, with the trunk bent slightly forward and the head thrown back a little. This position brings the axis of the larynx and trachea in as direct a line as possible with the axis of the mouth. Brünings' esophagoscope (see p. 889 et seq.) is quite as, or even more, suitable for autoscopy than Kirstein's original instrument. The only thing necessary is to leave out the inner tube and use simply the spatula-shaped tube of the instrument. Experience has led Kirstein to recommend the instrument pictured in Fig. 351 (a simple tongue spatula with a special groove) for most cases where direct laryngoscopy is advisable. The

illumination is furnished by the ordinary head-mirror. The advantage of Kirstein's method is that the parts are seen more naturally than by a mirror, with richer and more vivid shades of color. Nevertheless, the author is convinced that direct laryngoscopy will never usurp the place of mirror laryngoscopy. The appli-

Fig. 350.—Technic of autoscopy (Kirstein).

cation of the instrument is much more disagreeable to most individuals than indirect laryngoscopy, and almost always necessitates the employment of cocain. Besides, we can rarely view the entire larynx, and still less the trachea. In many cases the anatomic position of the parts is such that we do not see any further than to the epiglottis. The method furnishes very incomplete conclusions about the

Fig. 351.—Kirstein's tongue spatula for autoscopy; a, Lateral view; b, end of spatula, seen from above.

motility of the larynx, because the mobility of the parts is disturbed by the examination. Advantages of the method, however, are the directness of the picture and the ease with which the posterior parts of the larynx can be examined. These are very difficult to see in the ordinary laryngeal mirror, and, if seen, are sharply foreshortened;

they are very important in the diagnosis of initial tuberculosis affecting the arytenoid folds. Still other advantages are that direct laryngoscopy can be usually accomplished quite easily in small children; that in difficult cases the examination can be effected under chloroform anesthesia; that it decidedly simplifies intralaryngeal operations, and that it allows of such operations to be carried on under anesthesia.

Kirstein has even succeeded in introducing a small, so-called subglottic mirror into the larynx of patients who have been cocainized. He attached this with a long rod to the autoscope, and was able to examine the inferior surface of the vocal cords.

It must be acknowledged that considerable practice is necessary for orthoscopy as well as for the mirror examinations. To any one who is accustomed to the indirect or mirror laryngoscopy, the direct picture is so unusual that it is quite difficult to orient properly the apparently transposed parts, and still more difficult to correct certain habits of movement in the application of instruments, etc.

BRONCHOSCOPY

The procedure of bronchoscopy has recently been so perfected that it is possible to inspect the interior of the bronchi by means of an endoscopic appliance, which may be introduced either through the intact larynx or through a tracheotomy wound. Although this procedure has already been proved to be of considerable value, particularly for the extraction of foreign bodies, it will not be described, since it is difficult of application by the general practitioner. The most suitable instrument for bronchoscopy is the one invented by Brünings, and used for esophagoscopy as well. (See p. 889.) The only change necessary is to use thin and short tubes in the instrument instead of the longer and thicker ones with which the esophagus is viewed.

COMBINED LARYNGOSCOPY

Kirstein and, later, Leo have recommended a combination of direct and indirect laryngoscopy, under the name of "combined laryngoscopy," for cases which are very difficult to examine. The base of the tongue is depressed with the spatula of the orthoscope, and then the laryngoscopic mirror is introduced much farther down into the depths of the throat opposite the epiglottis.

RHINOSCOPY

The nasal cavities can be examined from in front and from behind within the pharynx. In the former case we speak of *anterior rhinoscopy*; in the latter case, of *posterior rhinoscopy*.

For **anterior rhinoscopy** we employ a nasal speculum to dilate the nasal openings a little, and then illuminate the nasal cavities from

Fig. 352.—Fränkel's nasal speculum (one-half natural size).

in front by a light reflected from a head-mirror. In this way we can observe the nasal septum, the inferior and a part of the middle turbinate bone. Quite exceptionally we also can see a small part of the superior turbinate bone. A very serviceable nasal speculum is pictured in Fig. 352. Catarrhal conditions of the nasal mucous membranes are readily recognized by *anterior rhinoscopy*; also the dilatation of the nasal cavities

due to the atrophy of ozena, nasal polypi, and the peculiar vasomotor engorgement of the erectile tissues in nervous nasal affections and in hay-fever. The latter is especially pronounced in the inferior turbinate bone.

Posterior rhinoscopy depends upon the same principle as laryngoscopy. A cone of rays is thrown from the reflector upon a small laryngeal mirror, which is introduced behind the uvula, with its reflect-

Fig. 353.—Anterior rhinoscopic picture in empyema of left frontal sinus. Characteristic collection of pus lateral to the middle turbinate bone and high up in the upper position of the middle nasal fossa (after a colored drawing by R. Krieg, *Atlas of Diseases of the Nose*, Stuttgart, Enke, 1900).

Fig. 354.—Anterior rhinoscopic picture in empyema of right sphenoid sinus. Collection of pus, the site of which is typical for an affection of the sinus and of certain ethmoid cells (after a colored drawing by R. Krieg, *Atlas of Diseases of the Nose*, Stuttgart, Enke, 1901).

Fig. 355.—Anterior rhinoscopic picture in empyema of the antrum of Highmore. Bilateral collection of pus between the middle and the lower turbinate bones in the middle and lower portions of the middle nasal fossa. This site is characteristic for affections of this cavity and of certain sphenoid cells (after a colored drawing by R. Krieg, *Atlas of Diseases of the Nose*, Stuttgart, Enke, 1901).

ing surface turned upward and forward. This mirror reflects the illumination to the posterior nares and transmits the reflected image of these parts to the observer's eyes. The path of the rays of light and the position of the mirror are shown in Fig. 356. In regard to the practical application of *posterior rhinoscopy*, the following differences between it and laryngoscopy should be noted: The tongue should not be protruded; we use a very much smaller laryngeal mirror—perhaps

the smallest size; we must be very careful not to touch any part of the pharyngeal wall; and the mirror is introduced behind or below the

Fig. 356.—Course of light-rays in posterior rhinoscopy. Sagittal section of head.

soft palate, its reflecting surface being directed upward and forward. The patient simply breathes naturally with a relaxed palate and does

Diagrammatic in that to obtain a complete picture the position of mirror must be repeatedly changed; *S.n.*, Septum; *Ch.*, choana; *P.m.*, soft palate; *U.*, uvula; *C.i.*, lower turbinate bone; *C.m.*, middle turbinate bone; *C.a.*, upper turbinate bone; beneath each turbinate the corresponding fossa; *O.R.*, roof of pharynx; *T.*, opening of Eustachian tube; *W.*, promontory of tube; *R.*, Rosenmüller's fossa (after Schnitzler).

not intone. If the root of the tongue bulge upward, it may be depressed by means of a tongue-depressor, held by the examiner's left hand, or sometimes by the shaft of the mirror. By accustoming the patient to

this method, it will succeed just as well as in laryngoscopy, even in very difficult cases. If success be impossible otherwise, cocain may be employed.

Fig. 357 represents a normal picture in *posterior rhinoscopy*. The main object of posterior rhinoscopy is to observe: adenoid vegetations and tumors of the nasopharynx, nasal polypi, inflammatory affections

Above it, superior turbinate bone; 6, inferior turbinate bone; 7, fossa of Rosenmüller; 8, promontory of the tube; 9, pharyngeal opening of the Eustachian tube.

of the nasal cavities, alterations in the openings of the Eustachian tubes in middle-ear disease, etc. (See p. 901 in regard to completing posterior rhinoscopy by direct rhinopharyngoscopy.)

OPHTHALMOSCOPY

Without going into the technic of ophthalmoscopy, a description of the more important changes in the eye-grounds will be given:

In Plates 9 and 11 several of these conditions are pictured. The drawings have been generally made in the upright image, though they have been reduced to the size of the inverted image.

Plate 9, Figs. 1, 2, and 3.—Various forms or stages of optic neuritis and choked disk.

Fig. 1. Beginning Optic Neuritis.—The disk is congested, the temporal margin is slightly veiled and swollen, the veins are moderately dilated and tortuous, the arteries are somewhat contracted.

Fig. 2. Pronounced Optic Neuritis.—The disk is apparently enlarged, with ill-defined margins. It presents radial striations, and is opaque from exudates and hemorrhages; it is very congested and swollen. The veins are greatly dilated; the arteries very much constricted.

Fig. 3. Optic Neuritis of the Highest Grade—So-called Choked Disk.—The disk is ill defined. It is prominent, like a mushroom, and projects 2 to 3 mm. There is a difference in refraction of at least two diopters between the apex of the swelling and the surrounding retina. The vessels make a sharp bend at the papillary margin. The disk at its margin is gray. In the center it is covered by a white exudate, which masks the congestion. The veins are very much dilated and tortuous; the arteries

¹ Brühl and Politzer, *Atlas of Otology*, Saunders, 1906. .

are narrow. Both are covered by exudates in the center of the disk, and make their appearance at the margin. The central ends of the blood-vessels appear to taper. There are striated hemorrhages arranged radially on the disk and in the grayish surrounding retina.

Between Figs. 1, 2, and 3 there are only differences in grade. All three varieties may occur from local inflammations, as well as from an increase of intracranial pressure. Forms such as Fig. 1 are occasionally observed in hypermetropia and after overuse of the eyes, as a consequence of functional hyperemia. Pronounced forms like Fig. 3 are most frequently observed in conjunction with brain tumors and tuberculous meningitis following protracted and marked increase of intracranial pressure. Occasionally in these diseases forms like Figs. 1 and 2 are observed. The clinical conditions, therefore, speak against a sharp separation of the condition known as optic neuritis (Figs. 1 and 2) from that known as choked disk (Fig. 3).

Optic neuritis occurs in intracranial tumors (in 70 to 85 per cent. of the cases), in syphilis of the central nervous system (in 14 per cent. of the cases, presumably where an intracranial tumor or a basal gummatous meningitis is present), in tuberculous meningitis, rarely in purulent meningitis, in primary internal hydrocephalus, in case it leads to increased intracranial pressure, rarely in brain abscess and internal hemorrhagic pachymeningitis, rarely in traumatic intracranial hemorrhages; furthermore, in certain affections of the orbit, especially tumors (in the latter case combined with exophthalmos, and, in contrast to the other cases, occurring on one side only), in polyneuritis, in chronic nephritis, especially contracted kidney, in diabetes mellitus, in scrofula, in disturbances of menstruation, during pregnancy, and in labor; in chlorosis, in severe chronic and acute anemias due to hemorrhage, especially of gastric origin, and in acute infectious diseases. In the last-mentioned diseases, not depending upon intracranial lesions, the picture of ordinary neuritis or papillitis without pronounced swelling of the disk is common (Figs. 1 and 2).

For purposes of diagnosis it must be remembered that an optic neuritis, even in its most intense form, may coexist with unaffected vision. Hence the rule that in all cerebral affections the ophthalmoscope should be employed, even when no disturbance of vision is present. Furthermore, it must be mentioned that in brain tumors the size and the site of the tumor are not of exclusive importance for the development of a choked disk, but that the rapidity of growth and other unknown factors play as important rôles.

Fig. 4. Changes of the Eye-ground in a Case of Severe Purpura Hemorrhagica. Extensive hemorrhages with inflammatory changes of the disk. The disk is distinctly swollen. Its margins are completely obscured from the exudation, suffused with blood. There are numerous hemorrhages situated in the retina and arranged in a radiating fashion. The color of the hemorrhages varies from a pale red to a dark or even black red. Within the zone filled with hemorrhages, as well as in the region of the disk, the blood-vessels are invisible. In the periphery of the eyeground the veins are thickened and tortuous, the arteries constricted (not visible in the figure). The picture resembles that of a thrombosis of the central vein. In this case the comparative improvement of vision spoke against this diagnosis. A moderate degree of neuritic atrophy remained.

Fig. 5. Albuminuric Neuroretinitis.—This occurs in the various forms of chronic, more rarely acute, nephritis, generally in contracted kidney. The disk presents the signs of a neuritis. It is blurred, not especially swollen, hyperemic, ill defined. The veins are dilated, the arteries contracted. There are radiating hemorrhages in the disk and in the surrounding retina, with numerous white patches (fatty degeneration), especially in the neighborhood of the disk and in the peculiar characteristic star-shaped figure about the macula lutea. The changes in the region of the macula lutea furnish the anatomic explanation for the usually very pronounced loss of sight. It should also be mentioned that in nephritis the changes of the retina may occur without changes in the disk (pure albuminuric retinitis), as well as neuritic changes of the disk without changes of the retina (albuminuric retinitis). The changes of the retina and of the optic nerve in diabetes mellitus are often like those found in nephritis.

Fig. 6. The Eye-ground in Pernicious Anemia.—The fundus appears unusually pale, and is covered with numerous irregular retinal hemorrhages and a few white patches. In one place, as occurs frequently, a white spot occupies the center of a hemorrhage. The hemorrhages and the blood-vessels are represented somewhat too dark in the drawing. The former appear so pale in the pronounced anemia that they are recognized with difficulty and are frequently overlooked. This condition occurs in a variety of severe forms of anemia, most pronounced in the so-called pernicious anemia (see p. 826), but is also found in bothrioccephalus and ankylo-

stomum anemia, and in leukemia. The changes are not so intense and usually not so pronounced in the severe anemias of certain cancers of the stomach, and are practically absent in simple chlorosis.

Fig. 7. The Eye-ground in Hereditary Syphilis.—Perivasculitis of the retinal vessels and choroiditis. Perivasculitis is especially characteristic for syphilis. The vessels, especially the arteries, appear to be outlined in white, owing to thickening of their walls. In one place the changes are so pronounced that a vessel is converted into a white strand, through which the blood-current can no longer be observed. The picture presents the characteristic spots of choroidal atrophy, and pigment deposits in the choroid. The macula lutea is especially plainly visible.

Fig. 8. Choroidal Tubercle in Acute Miliary Tuberculosis.—The choroidal tubercles are characterized as ill-defined white spots, which become more intensely white with age, usually round, and measuring one-quarter to one-half a papilla in diameter. In the later stages they are larger, and their site is independent of the course of the blood-vessels. If they be situated in the region of a blood-vessel, they are covered by the latter. The drawing shows recent and old tubercles. Especially characteristic in cases where the nature of these structures is not clear is their sudden appearance and increase within a few days. They can be distinguished from retinal spots by their usually circular form and their ill-defined margins. In the case depicted in the figure, in addition to the miliary tubercles, there was a complicating tuberculous meningitis, which explains the hyperemic and blurred appearance of the disk (beginning neuritis). Contrary to a widespread belief, the presence of choroidal tubercles is a rarity in uncomplicated tuberculous meningitis. Choroidal tubercles in almost all cases point to the presence of a general miliary tuberculosis. The characteristic condition of a tuberculous meningitis is, on the other hand, optic neuritis or choked disk.

Fig. 9. Medullated nerve-fibers of the retina, presenting a white, glistening, flame-shaped figure, beginning at the disk and striated radially. In the upper part of the picture a retinal blood-vessel is partly covered by this white structure; otherwise, the eye-ground is normal. This condition is anomalous, but without functional significance. It must, however, be recognized in order to distinguish it from pathologic changes.

Plate 11 gives a summary of the ophthalmoscopic pictures occurring in the various forms of optic atrophy, which are of great diagnostic interest.

Fig. 1. Simple Atrophy of the Optic Disk.—The disk is white and shining, the margins are unusually sharp, the light scleral ring is visible, especially on the temporal side, the lamina cribrosa appears as a glistening network, including angular, grayish areas representing bundles of atrophic nerve-fibers. The excavation of the atrophic disk is shallow, like that of a plate, and therefore recognized with difficulty. The color of the disk is usually most pale about the entrance of the blood-vessels and in the temporal half of the disk. The caliber of the blood-vessels usually remains normal. The very small blood-vessels which furnish nutrition to the disk are usually very few and fine. The large vessels, especially the arteries, usually diminish in size only after the atrophy has existed for a long time. The atrophic excavation of the disk develops generally only in the later stages, beginning at the margin of the disk and gradually proceeding to the center.

To distinguish this simple atrophy from inflammatory atrophy it is of importance to note the normal condition of the blood-vessels, the visibility of the lamina cribrosa, the well-defined margins of the disk, with distinct scleral ring.

Simple atrophy occurs most frequently in tabes dorsalis and in progressive paralysis; furthermore, in the so-called primary gray degeneration of the optic nerve without spinal or cerebral symptoms. In some cases of multiple sclerosis simple optic atrophy has occurred; in others, neuritic atrophy. It should further be mentioned that simple atrophy of the optic nerve may occur if there be an interruption in the course of the optic nerve or of the optic tract, as in chronic hydrocephalus, where the distended infundibulum presses upon the chiasm.

Fig. 2. Atrophy of the Optic Disk After Embolism of the Central Artery, Following Ligation of the Common Carotid in a Case of Pulsating Exophthalmos.—Complete blindness. The disk is grayish-white. The margins have a distinct scleral ring; the lamina cribrosa is visible. In the center the central canal appears as a grayish dot. The vessels are contracted to mere threads.

Fig. 3. Atrophy (Pressure Atrophy) of the Optic Nerve in Glaucoma Simplex.—Complete blindness. The disk is grayish white; the lamina appears in the center. The entire disk is deeply excavated. The vessels make a sharp bend at the margin and disappear in the depth. A few again appear at the bottom of the excavation; some are broader and lighter in color because of differences in refraction. The

veins are somewhat dilated, the arteries slightly contracted. There is a yellow area with several pigment spots about the excavated disk (halo glaucomatosus).

Fig. 4. Neuritic Atrophy of the Optic Disk.—Incomplete blindness. The disk appears dull white; the nasal half is still slightly red in color. The margins of the disk are ill defined, without a distinct scleral ring. The lamina cribrosa is not visible. The vessels are moderately contracted, especially the arteries. Some are surrounded by narrow white lines characteristic for sclerosis of the vessel-wall. Occasionally pigment is present in the form of small spots at the margin of the disk. These features (ill-defined margins of the disk, contraction of the blood-vessels, invisibility of lamina cribrosa and scleral ring) differentiate this form from that of simple atrophy.

Any inflammation in the course of the optic nerve may lead to neuritic atrophy. In some of the cases of multiple sclerosis, as has been above stated, the atrophies observed have been of an inflammatory type. The illustration is of one of these cases.

Fig. 5. Papillitic Atrophy.—Blindness. The disk is dull white and uniformly discolored. The margins are even less sharp than in Fig. 4, passing over into the choroidal changes which surround the disk (the pigment is often lacking; in other cases it is deposited irregularly). The lamina cribrosa is invisible. The vessels are distinctly contracted. These changes represent simply a higher grade of neuritic atrophy (Fig. 4), which is spoken of as papillitic atrophy, because in its occurrence the disk is included in the neuritic process. Consequently papillitic atrophy is a frequent sequence to true choked disk, especially in brain tumors. As the choked disk proceeds to atrophy, the disk remains swollen for some time, the vessels show a distinct bend, as in Fig. 3, Pl. XII, while it gradually assumes more and more the character of papillitic atrophy (whitish discoloration, narrowing of the blood-vessels). In this condition the color of the disk is often a dirty grayish yellow.

Fig. 6. Papillitic Atrophy after Thrombosis of the Central Retinal Vein, Following Chronic Meningitis.—The disk is discolored, grayish white. Its margin on one side is distorted. It is surrounded and partly obscured by extensive changes in the choroid and pigment accumulations. In the center the central canal appears as a grayish dot. The vessels are converted into thin white strands (progressive organized thrombosis). In this form the condition of the blood-vessels is characteristic.

Fig. 7. Retinal Atrophy in Old Chorioretinitis.—The latter affection in this case was the result of unusually prolonged lactation, and presumably developed upon a syphilitic basis. In any case, it resembled certain late stages of syphilitic chorioretinitis. Incomplete blindness. The disk is of a uniformly dirty-yellowish-gray color. The margins in this case are sharply defined; sometimes, however, they are blurred. The lamina markings are not visible. The vessels are unusually narrow. The retina and the choroid are very much changed, the choroidal vessels presenting evidences of sclerosis. The intravascular spaces are dark. There is moderate pigment accumulation in the retina.

Similar changes of the disk to those which have just been described may occur in retinitis pigmentosa and in other chronic inflammatory processes of the retina, as well as in detachment of the retina. The retinal and choroidal changes are characteristic in differential diagnosis from other optic atrophies.

Fig. 8. Atrophic Discoloration of the Temporal Half of the Disk in Alcoholic Amblyopia (Central Scotoma for Green and Red; Vision Very Much Reduced).—The temporal half of the disk is grayish white, the margins are sharp, the scleral ring is distinct, the lamina is not visible, and the vessels are of normal caliber.

This is a case of atrophy of the papillomacular bundle of the optic fibers. As it occurs through toxic influences (especially alcohol, but also tobacco, stramonium, carbon disulphid, and chloral), 16.5 per cent. of alcoholic subjects and 65 per cent. of patients with alcoholic amblyopia show these changes. Similar changes have been observed in diabetes mellitus and after taking cold. It is important to remember that in 1 per cent. of persons with normal sight a somewhat similar pallor of the temporal half of the disk may be observed.

While in this illustration toxic atrophy of the temporal half of the disk presents the characteristics of a simple atrophy, it may in other cases show certain peculiarities of an inflammatory atrophy (indistinct margins, slight sclerosis of the vessels, as in Fig. 4). Both forms are frequently spoken of as retrobulbar neuritis, from the supposition that the cause of the changes is a retrobulbar optic neuritis. The name, however, is not quite correct, as an inflammation of the optic nerve behind the eyeball may lead to changes in the entire disk, in the form of a simple (descending atrophy) or of a neuritic atrophy.

EXPLORATORY PUNCTURES AND HARPOONING

EXPLORATORY PUNCTURES

By an *exploratory puncture* we mean the introduction of a fine hollow needle, attached to a test puncture or aspirating syringe, into a diseased area, and a subsequent aspiration in order to examine the character of the tissues, and especially to determine the presence or absence of collections of fluid. In puncture to obtain fluid in subcutaneous edema no aspiration is employed.

SYRINGES FOR EXPLORATORY PUNCTURES

The appropriate syringe is a little larger than the ordinary hypodermic syringe, and is furnished with a longer and rather coarser needle. The hypodermic syringe may also be used if such a large needle be fitted to it tightly. A syringe which contains 5 to 10 cc. of fluid is large enough to furnish adequate aspiration force to withdraw even quite solid fragments of tissue and sufficient fluid for a satisfactory chemical or bacteriologic examination. The essentials for a serviceable exploratory puncture (or aspiration) syringe are the following: The glass cylinder should have a uniform caliber, so that the piston fits accurately. The packing must be absolutely tight, so that if the end be closed and the piston withdrawn, the latter will slip back quickly into its former position by the force of suction. The needle must be fitted on air-tight, so that the same test can be successfully applied after the needle is screwed to the syringe. If the material withdrawn is to be examined bacteriologically, the syringe must be carefully sterilized. This can most easily be done with the glass syringes furnished with a metal piston or asbestos packing, and asbestos piston. The most perfect are furnished with a contrivance for compressing the asbestos packing against the cylinder, so that it can be made as tight or as loose as is desired. The cannulas or needles should be of an appropriate size. This is not always the case with the varieties on sale. They should be 6 to 7 cm. ($2\frac{1}{2}$ – $2\frac{3}{4}$ in.) long (not including the connecting portion) and about 1 mm. ($\frac{1}{16}$ in.) external diameter, so that the puncture will be sufficiently large. Such fine needles practically obviate the possibility of any danger.

METHOD OF MAKING EXPLORATORY PUNCTURES, AND THE GENERAL RESULTS OBTAINED

Before each attempt the needle must be carefully disinfected according to the strictest surgical rules. This means that after being used it should be carefully cleansed in water, then boiled for ten minutes and kept in alcohol. If the needle be well nicked, it is not at all injured by this treatment. After use, the syringe itself is best cleansed and prepared for future use in the same manner. The pistons of syringes with asbestos packing must be loosened by means of the appliance described above before boiling, otherwise they may swell too much. Metal pistons are best removed altogether before sterilization by boiling,

so that the glass of the syringe may not be cracked. In boiling up these instruments it must not be forgotten that to insure perfect sterilization the needle as well as the syringe must be filled completely with water, all air-bubbles being thus driven out. If the needle and the syringe are kept in alcohol, all traces of it must be removed before use by rinsing them out with sterile water, for otherwise serous fluids obtained by aspiration may become clouded by the alcohol and thus lead to erroneous conclusions. Traces of water remaining after rinsing out the syringes must also be removed, otherwise one is never sure whether traces of fluid found after aspiration were present in the syringe before the operation or have been obtained from the tissues.

Much discussion has taken place in reference to the disinfection of the skin which should precede all exploratory punctures. It is well known that a strict and perfect disinfection of the skin cannot be attained even by the methods used in the preparation for major operations (the use of soap, alcohol, sublimate solution, etc.), and, indeed, such disinfection is quite unnecessary for such a small operation as an exploratory puncture. The method which has been used for many years in the author's clinic consists in covering the portion of the skin with a layer of 1 : 1000 sublimate solution by means of a slab, without rubbing the skin at all; the puncture is then made through the skin disinfected in this manner, and after the needle is withdrawn, a drop of the same solution is placed on the puncture hole. In the antisepsis of an exploratory puncture the important thing is simply to introduce a trace of the antiseptic solution into the wound so as to prevent the growth of bacteria into it. The author makes use of an alcoholic solution of the sublimate, though this is less suited for purposes of disinfection than a watery solution. The fact is, however, that it is not at all the author's purpose to disinfect, but simply to have a trace of the sublimate remain in the puncture wound after the alcohol has evaporated; an alcoholic solution is best suited to this end because, as is well known, only such solution will stick to a greasy skin. Thorough rubbing with a disinfecting solution, a procedure that is often recommended, can only have one result: the small epithelial scales detached by rubbing and not perfectly disinfected are driven deep into the skin by the needle. The author even makes it a point to warn his students not to employ this method of skin disinfection. The puncture wound is finally covered with a piece of cotton dipped into a 1 : 1000 watery solution of the sublimate.

The skin should first be stretched tightly and the needle inserted perpendicular to the surface, and not too quickly, so as to avoid any bony parts by slightly altering the direction. During the introduction of the needle we should pay special attention to the resistances met with at the different depths. We are then able to select the appropriate moment for aspiration; this should be when we feel that the needle has passed all obstructions, entered a cavity, and is freely movable laterally. Such palpation with the needle should never be neglected. Sometimes, however, a slight amount of fluid is obtained while the needle seems to be sticking into perfectly solid tissue. We should not desist if we obtain no fluid by aspiration, provided we have good reason to believe that fluid is there. Frequently we have penetrated too far or not far enough, and a slight push or withdrawal of the needle will be sufficient to obtain fluid. In other cases we withdraw the needle partially and then point it in a slightly different direction. If the aspirating force of the syringe

has been completely spent by the gradual withdrawal of the piston, the latter must again be pushed forward into the syringe after first unscrewing it from the needle, so as not to introduce any air into the tissue. At the same time we must be careful to notice any chance movements which may be imparted to the point of the needle by parts which have been punctured or touched, such as the lungs, diaphragm, liver, spleen, heart. Such movements are of the greatest importance for diagnosis. Furthermore, it pays to note the behavior of the piston during an aspiration which does not yield any fluid. If it can be withdrawn only by overcoming a certain amount of resistance, and if, when let loose, it springs forward again because of the pressure of the external atmosphere, it may be concluded that the needle has entered solid tissue, unless its lumen is obstructed. If, on the other hand (the syringe and connections being air-tight), the piston is found to be easily movable and no fluid enters the syringe, it may be concluded that the needle has entered an air-containing space, such as is found in pneumothorax, the lumina of bronchi, pulmonary cavities, gas-containing abscesses, and the lumina of intestines or of the stomach. However, the air-tightness of all connections must first be made sure of before such a conclusion is justified. If the first puncture be unsuccessful and the examiner be still convinced of the presence of fluid in the vicinity, the procedure should be repeated at an adjoining spot after he has again more carefully examined the locality. If not a drop of pus has been obtained by the first puncture and a severe suppurative infection is not present, the same cannula may be again used in case of necessity. Otherwise, it is best to use a new cannula for each new puncture or to disinfect the old one by boiling before using it again. In every case where we find fluid it is advisable to aspirate a sufficient quantity to perform all the necessary examinations. If the needle enter solid tissue, and we wish to examine this tissue histologically, we can generally obtain a specimen by pulling the needle back and forth a few millimeters, twisting it at the same time so that it acts like a cork-borer. Then with sufficiently strong aspiration we can suck out a fragment of the tissue large enough for microscopic examination. In this attempt the needle must be very carefully withdrawn after the aspiration. Its contents, which often consist of quite small tissue fragments, can usually be forced out upon a glass slide by a vigorous push of the piston. The fragments may then be teased apart and examined microscopically. Whenever, in any exploratory puncture, aspiration brings no fluid, we should never neglect to examine the contents of the needle carefully in the way described. Aspiration frequently obtains only tiny flakes of pus from purulent infiltrated tissue or from thick collections of pus. Such flakes microscopically demonstrated are oftentimes quite sufficient for diagnostic purposes.

If the object be to obtain some fluid from edematous subcutaneous tissues for examination, one of Southey's cannulas, such as are used for therapeutic purposes in treating edema, may be employed. The cannula armed with the stilet is introduced perpendicularly into the skin, and when the stilet is removed, the fluid usually falls drop by drop from the cannula. A small tube may be attached to the latter and the fluid conveyed directly into a beaker.

Where we obtain a large amount of fluid from an exploratory puncture, the first essential always is to examine this fluid macroscopically;

thereby we determine definitely whether it is serous or purulent,¹ clear or turbid, colorless or colored, bloody, bile stained, odorless or foul-smelling, and, if purulent, whether it contains the characteristic granules of actinomycosis. (See p. 724.) In turbid serous fluids the macroscopic appearances are often sufficient to decide between a purulent and a fibrinous turbidity, since the latter is characterized by the presence of flocculi. Otherwise a microscopic examination must be made. This will also furnish information in reference to the so-called chylous character of a fluid, *i. e.*, a turbidity caused by the presence of minute particles of fat. Chylous fluid in a cavity may be due to a number of different causes. As a result of a stasis of lymph in the thoracic duct, the fluid may become admixed with chyle by diapedesis without there being any solution of continuity of the lymph-vessels. In tuberculosis or malignant tumors of the pleura or of the peritoneum the thoracic duct or some of the smaller lymphatic vessels may be ulcerated by the destructive process and the chyle poured out into the affected cavity. In all these cases, as in chyluria, the *admixture with chyle* may be recognized by the microscopic examination of the fluid. The fat is not present in large drops, but in the finest droplets, which in size somewhat resemble micrococci, and usually exhibit the so-called Brownian movement. In addition to the fact that they do not stain well in dry preparations (see p. 715), they may be differentiated from microorganisms by their great quantity, since such a large number of microorganisms could scarcely be present in a non-purulent fluid. They also show an additional peculiarity in that they tend to collect in a layer upon the upper surface of the fluid when it is allowed to stand. Chemical tests may also be applied after removing the fat from the fluid by agitation with ether. From a chemical standpoint it should also be noted that amounts of sugar greater than those found in the blood are not to be expected in chylous fluids, since sugar leaves the intestine through the veins and not through the lymphatics. True chylous fluids have also been found in cavities under circumstances which have not yet been explained, there being neither a lymph stasis nor a rupture of a lymphatic. In these cases the serosa is possibly abnormally permeable to fat-particles, which, as is well known, are present in large numbers in normal blood after the ingestion of food. (See p. 811.) These true chylous exudates and transudates are not to be confounded with fluids in which the turbidity depends upon the presence of larger fat-globules. In the latter instance the finding of cells containing fat-droplets demonstrates that the admixture is dependent upon fatty degeneration of endothelial cells or of tumor cells.

Microscopic examination will also give information in reference to the *presence of leukocytes* and *admixtures with blood* which would escape macroscopic inspection (see p. 918 et seq.), and to the presence of cholesterin crystals in old serous exudates (Fig. 278, *b*); it will also reveal the presence of *hematoidin crystals* (Fig. 278, *d*) in purulent collections (pleural empyemata, subphrenic abscesses, pulmonary ab-

¹ Although it seems very simple to differentiate a serous from a purulent exudate by means of exploratory puncture, errors may easily be made, since thin, purulent exudates tend to settle, so that if the puncture be made high up, nothing but a clear serum may be obtained; the pus-corpuscles sink to the bottom of the cavity. In doubtful cases it is consequently advisable to make a second puncture at a lower level.

scesses, and empyema of gall-bladder), and particularly the presence of *bacteria*. Dry preparations should be made. (See p. 715.) It is best to select fibrinous flocculi obtained by centrifugation, for the bacteria are caught in the meshes of the fibrin network. When a serous exudate contains but few bacteria, their discovery may be facilitated by centrifugation in accordance with the method suggested by Ilkewitsch for the examination of sputum for tubercle bacilli. Glacial acetic acid is added to the fluid, and the bacteria settle with the precipitate. In addition to the foul odor, the microscopic demonstration of food-particles and innumerable bacteria in the fluid obtained from the peritoneal cavity by exploratory puncture is of great importance for the demonstration of a perforation of the stomach or intestine. [Exploratory puncture of the peritoneal cavity has been entirely superseded by an exploratory laparotomy.—Ed.] The microscopic demonstration of particles of tumors in fluids obtained by puncture is also of importance. They may be found as isolated cells, differing from the normal endothelium, or as peculiar cell conglomerations, the latter being evidence of a much more positive character.

When a serous fluid is obtained, it is sometimes of importance to determine by the examination of this fluid whether it be an *exudate* or a *transudate* (in cases where the determination is impossible by other means). This may be done by estimating the protein content, determining the specific gravity and the number of leukocytes, and demonstrating the presence of a protein which is precipitated by acetic acid.

The protein contained in the fluid withdrawn is most accurately estimated by weighing the precipitated protein according to the method mentioned upon p. 613. Esbach's method, although reasonably accurate for urinary examination (p. 615 et seq.), is not applicable for serous fluids. If it be used, however, the fluid, rich in protein, should be diluted with urine in order to preserve the relations (specific gravity, salt content) of the usual urinary test. Reiss has recently worked out a method of estimating the protein content of puncture fluids with the aid of Pulfrich's immersion refractometer.¹ (See p. 614.) A great many statements are to be found in literature² upon the protein content of exudates and transudates. It is practically agreed that hydropic transudates contain much less protein than inflammatory exudates. Nevertheless, most observers contend that the distinction is not sufficiently sharp, and that the rules are not sufficiently general in their application to permit of a differential diagnosis between exudates and transudates. Runeberg,³ however, contends very emphatically that the protein content in serous fluid is of distinct diagnostic significance. He believes that the difficulties which have thus far militated against the diagnostic importance of the protein content mainly depend upon the fact that various observers have contrasted merely inflammatory with hydropic effusions, whereas in reality the

¹ Reiss, Brechungsquotient des Blutserums als Indicator für Serumgehalt, I. A. D., Strassburg, 1904; *ibid.*, Arch. f. exp. Path., 1904, vol. li. His tables are printed in Zeiss' prospectus of Pulfrich's refractometer.

² Compare, for example, Vierordt, Daten und Tabellen, 1888; Bernheim, Virchow's Arch., vol. cxxxvii, and others.

³ Von der diagnostischen Bedeutung des Eiweissgehaltes in pathologischen Trans- und Exsudaten, Berlin. klin. Woch., 1897, No. 33.

distinction must also be made between—(a) congestion transudates and (b) hydremic transudates. Besides, these observers have not heeded the possibility of a combined origin for such effusions. Runeberg's experience shows that the estimation of the protein content of the fluid is very essential in the diagnosis of such combined forms. He determined that the protein content was 4 to 6 per cent. in inflammatory exudates (including tuberculosis and carcinomatosis of the serous membranes); whereas the protein content in pure congestion transudates varied between 1 and 3 per cent., and in pure hydremic transudates, from 0.1 to 0.3 per cent., scarcely ever exceeding 0.5 per cent. These figures are sufficient for the diagnosis of fresh effusions, but to avoid incorrect conclusions it should be remembered that the protein content in old congestion transudates rises under high pressure, where they are undergoing absorption, or where changes in the serous membranes, nearly related to inflammatory changes, are developed as a result of chronic congestions (connective-tissue sclerosis, endothelial desquamation). In such cases we are in reality dealing with combined forms, and their occurrence will explain most of the apparent contradictions to the above-mentioned rules.

These combined forms are naturally much more difficult to diagnose, but, as a matter of fact, the protein content of the fluid really enables us, at least, frequently to analyze clinically such a disease picture, and is especially valuable in the determination of the proper therapy. Alterations of the protein content during the same clinical observation may furnish valuable conclusions. For example, they may suggest the appearance of a carcinomatous peritonitis as a complication of a portal stasis produced by carcinoma, or, again, the addition of congestion to a pure renal hydrops. The great difficulty in the practical application of these important facts is the complexity of an exact quantitative protein estimation; it is too difficult for bedside work. To overcome this difficulty Runeberg has adopted a method which, although it does not measure the protein content exactly, is sufficiently accurate for the purpose in view. He adds a few drops of nitric acid to the fluid in a test-tube, and then judges by the shape and consistence of the precipitate. In exudates which depend upon a local affection of the serous membrane (inflammation, tuberculosis, carcinomatosis) the precipitate forms thick, heavy clumps which quickly sink to the bottom of the glass; in congestion transudates, abundant large flocculi, which ordinarily sink to the bottom also, but which are more loosely and more lightly precipitated; in pure hydremic transudates, merely a decided opalescence or small, loose flakes which float for a long time in the fluid. Evidently a certain personal experience, acquired from sharply defined cases, is essential for correctly differentiating the mixed forms. Runeberg also emphasizes in the differentiation, in addition to the protein content, the precipitation with acetic acid (see below).

F. A. Hoffmann¹ has investigated the protein content of fluid in edema. He found that ordinary edematous fluids occurring in cachexia or stasis usually contain 0.1 to 0.8 per cent., whereas in kidney disease a content of less than 0.1 per cent. was found.

The *specific gravity* of serous fluids is approximately proportional to the protein content, and may, therefore, be utilized for a rough esti-

¹ Hoffmann, Deut. Arch. f. klin. Med., vol. xlv, part 4.

mation of the latter. According to Ruess,¹ the following figures represent the relation between the specific gravity and protein content:

Specific gravity.	Protein content.
1018.....higher than	4.0 per cent.
1015.....lower than	2.5 "
1012....." "	1.5 to 2.0 "
1010....." "	1.0 to 1.5 "
1008.8....." "	0.5 to 1.0 "

An ordinary urinometer (p. 551) is sufficiently accurate and the most convenient instrument to employ for estimating the specific gravity. A sufficient quantity of fluid is obtained, before the needle is withdrawn, by repeated suction and emptying of the syringe. Providing a fine needle, such as recommended above, be used, the syringe may be disconnected without risk of producing pneumothorax even in pleuritic effusions under negative pressure, because the internal friction of the needle is too great to be overcome by the difference between the latter and that of the outside air. If necessary, the specific gravity may also be estimated from a smaller quantity of fluid by the pyknometric method described for the blood on p. 735, or by Hammerschlag's method, although the latter procedure is more difficult. It is probable that the amount of protein precipitated by acetic acid from a fluid obtained by aspiration depends on the number of leukocytes therein or the quantity of their products of decomposition.

The demonstration of this protein was first shown by Primavera and Rivalta² to possess a certain importance for the differentiation between exudates and transudates. An abundance of this protein is evidence in favor of an inflammatory exudate and against a transudate. Rivalta's test is performed in the following manner: An exceedingly dilute aqueous solution of acetic acid (2 drops of glacial acetic acid to 200 cc. of water) is prepared, and a drop of the fluid to be examined is allowed to fall into this solution from a glass rod. If the fluid contain a considerable quantity of the substance in question, the drop immediately sinks to the bottom of the acid solution, producing a turbidity resembling a cloud of cigar smoke. If the questionable substance be absent, no turbidity appears; if present in slight amount, the cloudiness is very slight and of gradual development. Following the suggestion of Paijkull, Runeberg demonstrates the presence of this substance simply by the addition of a few drops of acetic acid to the fluid. In inflammatory exudates a more or less marked turbidity appears, while in transudates this is very slight or entirely absent. The nature of this substance is still under discussion. Rivalta formerly believed it to be nucleo-albumin, but now³ regards it as a mixture of euglobulin (paraglobulin) and pseudoglobulin. Umber⁴ thinks it is a mucin, and designates it as serosamucin, while Stähelin⁵ believes that it is related more closely to the globulins than to the mucins. It would seem that the different authors are not working with the same substance, since Rivalta, for example, expressly states that it is soluble in a slight excess of acetic acid, while Umber declares the

opposite to be the case. In regard to the reaction (Nonne-Appelt) recommended in the case of cerebrospinal fluid, see p. 941.

Another important criterion for the inflammatory origin of a serous fluid is its content of fibrin ferment, which is manifested by the spontaneous formation of fibrin either before or after the withdrawal of the fluid.

The presence of *bile-pigment* in the fluid may also be important, particularly so when the biliary passages perforate into the peritoneal or pleural cavities. In addition to the characteristic yellowish-brown or greenish discoloration, the reactions for the bile-pigments may be demonstrated by the same methods as those employed for the urine.

For a *bacteriologic examination* of aspirated fluid the culture method is to be recommended in addition to the above-mentioned microscopic examination, because with serous fluids the latter rarely furnishes a positive result. With a purulent exudate, except with purulent tuberculosis, the ordinary stick or streak inoculation frequently furnishes positive results; but with serous exudates, which contain very few micro-organisms, a much larger amount of fluid must be employed for inoculation, just as in the bacteriologic examination of the blood. (See p. 814.) A number of drops, from 5 to 10, may be squirted from the syringe directly into culture-tubes containing slant-agar gelatin or bouillon. Plate cultures may be employed, as is mentioned in the examination of the blood. In regard to the technic, text-books on bacteriology should be consulted.

Gas as well as fluid is sometimes withdrawn in punctures; for example, in abdominal punctures when the point of the needle penetrates the stomach or the intestines, in pyopneumothorax, in pulmonary cavities in case the cannula has entered a bronchus, and in abscesses which contain gas. This finding may have some diagnostic significance, but only when we are sure that the gas was aspirated through the needle and not through a leak in the syringe. (See p. 911 for a method of testing the syringes.)

In addition to the determination of the presence of fluid collections, as well as their peculiarities and characteristics, exploratory punctures are especially important in order to decide upon the spot for attempting therapeutic punctures. Immediately before any therapeutic puncture we should demonstrate the presence of fluid by an exploratory puncture exactly at the spot to be selected, and should demonstrate the free mobility of the puncture needle in a cavity. Otherwise we run a danger of causing some injury in a therapeutic puncture with the coarse and much more injurious instruments, should we penetrate, for example, local adhesions of the lungs or heart, or in abdominal punctures, a full intestinal coil.

THE EXAMINATION OF THE CELLS AND FERMENTS FOUND IN PUNCTURE FLUIDS

(See p. 937, Lumbar Puncture, for description of cerebrospinal fluid.)

A method of investigation rejoicing in the promising title of *cytodiagnosis* has been introduced by French writers, particularly by Widal and his pupils. It consists of the study of the character and number of the cellular constituents of exudates and transudates, and of subsequent deductions from these studies as to the nature of the fluids.

The sediment obtained by gravity or centrifugation is either subjected to direct microscopic observation, or, when greater accuracy is required, is utilized for the

preparation of cover-glass specimens. Jenner's stain is well adapted for staining such preparations. In such dry preparations the relative numbers of the different varieties of cells may be observed, particularly of the leukocytes. For this purpose the movable stage or Ehrlich's ocular diaphragm (p. 794) may be employed. The absolute numbers may be determined by counting the cells according to the method used in estimating the number of white cells in the blood, the fluid being used undiluted or diluted, as is best in each individual case. (See p. 757.)

If the exudate coagulate rapidly soon after its withdrawal, Widal advises that the coagula be broken up by agitation with glass beads before centrifugation. It is doubtful whether accurate results are obtained by this procedure, since a great many of the cellular elements will always remain embedded in the coagula. Instead of utilizing this procedure, the examiner can prevent the coagulation of the fluid by aspirating it into a syringe half filled with ammonium oxalate solution, sodium citrate solution, leech infusion, or a solution of hirudin. The ammonium oxalate solution consists of 2 parts of ammonium oxalate to 1000 parts of normal saline solution. The leech infusion is prepared by cutting the head of a leech into small pieces and rubbing them up in a mortar with sand. This mixture is then diluted with cold normal saline infusion, allowed to stand for an hour, during which time it is frequently stirred, and finally filtered. Instead of this infusion, physiologic saline solution, to which a small amount of commercial hirudin (1 mg. to a few cubic centimeters) has been added, may also be employed. The employment of these agents preventing coagulation is to be particularly recommended when the sediment is obtained by gravity rather than by centrifugation, since in the necessary interval some of the leukocytes may become disintegrated and be caught in the fibrin network. Instead of preparing dry smears from centrifuged or sedimented puncture fluids N. Jagic has lately recommended the staining of the sediment in the moist state while it is still contained in the centrifuge tube. He uses the Giemsa stain¹ for this purpose. The method employed by him is as follows: After thoroughly centrifuging the fluid that is to be examined,² the plasma is poured off carefully and the sediment is shaken in the centrifuge tube with about 10 cc. of 2 per cent. formaldehyd solution. The mixture is then centrifuged once more, and the formaldehyd solution is carefully poured off or removed by a pipet. The sediment is then mixed with about 1 cc. of Giemsa's solution diluted with the same amount of water. The mixing is done by means of a platinum wire, for about five minutes, this period being sufficient for staining, and then a drop of the stained fluid spread on a slide and covered with a cover-glass is examined microscopically. If the stain be not sufficiently deep, 1 or 2 drops of the concentrated Giemsa solution may be added to intensify it. The preparation may be ringed with gum shellac and thus preserved for some time.

The morphologic elements demanding our attention in cytodiagnosis are: erythrocytes, the various kinds of leukocytes, endothelial or epithelial cells, and the cells of tumors.

The microscopic study of the erythrocytes furnishes but little additional information to that obtained by a macroscopic inspection of the fluid. The presence of blood may be demonstrated also by chemical means (for methods employed see section upon Urinary Examination), but the microscopic demonstration is a more refined diagnostic procedure. Large quantities of blood are found in carcinomatous, tuberculous, and nephritic exudates, in the transudates of marked venous congestion, and in all the hemorrhagic diatheses.

The literature³ of cytodiagnosis is already quite extensive, and the greatest discussion has been in reference to the leukocytes contained in the fluid. It is to be supposed *a priori* that a large number of leukocytes speaks for an inflammatory origin of the particular fluid, and that the number of leukocytes is proportional to the intensity of the inflammation, as may be easily verified by studying the occurrence of suppuration in any serous exudate. Cytodiagnosis, however, has gone much farther, and just as certain blood-pictures have been accepted as characteristic of certain diseases of the blood and hematopoietic organs, definite cytodiagnostic formulas, based upon the nature and relative numbers of the leuko-

¹ See p. 779 et seq. The solution may be obtained ready-made for use from Grübler, in Leipzig.

² The addition of solutions to prevent coagulation is likewise advisable. (See above.)

³ See Brion, Centralbl. f. allg. Path., 1903, vol. xiv, b. 609; H. Königer, Die cytologische Untersuchungsmethode, etc., Jena, G. Fischer, 1908. The latter work contains a detailed review of the literature.

cytes contained in the fluid in a cavity, have been suggested for the diagnosis of the underlying disease process. This is particularly noticeable in the attempts that have been made to differentiate tuberculous exudates, non-tuberculous exudates, and the exudates of malignant tumors, from the relative numbers of the polynuclear and mononuclear elements.

It would seem that these efforts have gone too far, and that the empiric or statistic findings have not been tested by our knowledge of general pathology. Although we know that the emigration of polynuclear leukocytes is one of the essential characteristics of inflammation, it has not yet been decided whether mononuclear cells or leukocytes ever pass out of the blood-vessels. It is generally supposed that by far the greater number of the mononuclear cells are the result of regenerative processes which are associated with and consecutive to the inflammation, and that they originate in the lymphoid tissue which is found disseminated throughout almost all the viscera. In addition lymphocytes derived from the lymph are found in fluids obtained from cavities.

If we abandon the crude empiric or statistic standpoint from which the question of cytodagnosis is usually considered, and which leads to erroneous conclusions because it does not lay sufficient stress upon the different stages and degrees of the inflammatory process, it would seem that a large number of polynuclear cells is indicative of marked and recent inflammations, while a considerable quantity of mononuclear elements signifies either a milder degree and later stage of an inflammation or the presence of a non-inflammatory process.

In addition to red blood-cells, polynuclear cells, and lymphocytes there are often found in fluids obtained from serous cavities many mononuclear cells that probably represent endothelial elements derived from the serosa. Frequently, these cells still show the typical polyhedral shape, but, on the other hand, they may be degenerated or changed in form and structure because of swelling or shriveling. Usually they are rounded in shape and may be either discrete or in groups and ragged aggregations that have been termed "endothelial plates." Of course, the presence of endothelial cells in these fluids is evidence of desquamation, and may be interpreted as signifying some mechanical or chemical injury to the endothelial layer. But their number should not be used as a measure of the damage done in each particular case. Indeed, it may be that the opposite is more true, that is, the more extensive is the damage of the serous coat, the less cells are found in the fluid obtained from the cavity lined by it. This phenomenon is probably explained by the fact that the more severe chemical injuries to the endothelial cells are accompanied by diminution of the regenerative power in the cells; moreover, in severe injuries layers of fibrin take the place of the endothelial coat or simply cover it up; the endothelial cells, too, are numerically overwhelmed by the lymphocytes and leukocytes which originate from the deeper tissues. As a consequence, a preponderance of endothelial cells is seen especially in the purely hydropic transudates, such as arise in passive congestion or in disturbances of the kidneys, and also in such effusions as are caused simply by mechanical non-infectious factors. Examples of the latter type are found in effusions following trauma and those accompanying tumors, when due simply to the mechanical friction between the tumor masses projecting into the serous cavity and the serous coat of the latter. It is to be noted, finally, that occasionally the endothelial cells show well-marked macrophagic properties, taking up not only bacteria, but red and white blood-cells as well.

In addition to these varieties of cells we must finally mention tumor cells which may be found in fluids that appear in the serous cavities in the presence of tumors. The importance of these is, of course, diminished by the fact that surfaces of tumors do not necessarily shed their cells into the cavities even if the serosa itself be infiltrated by the new-growth. Moreover, it is often impossible to differentiate with certainty tumor cells from endothelial cells that have undergone various changes.

These general principles of cytology show that in each concrete case we must assume a critical attitude toward the various findings obtained by this method of examination, and place but little confidence in any set of "cytodiagnostic formulæ."

It consequently seems to the author that the predominance of either variety of cell in an exudate is less indicative of the etiology of the inflammation than it is of its stage and severity.

Besides the variations due to different stages of the disease, a great obstacle to the utilization of cytodagnostic findings is that the fluid obtained by aspiration by no means accurately represents the characteristics of the same fluid within the body and at the moment of its origin. It is well known that the cellular elements of a fluid may be so influenced by sedimentation within the body that a serous fluid may be obtained by exploratory puncture, although a complete evacuation of the accumu-

lation might demonstrate its purulent character. (See foot-note, p. 914.) Since the various kinds of leukocytes sediment with different degrees of rapidity dependent upon their variations in size, it follows that we cannot always depend upon their relative numbers as determined by a study of the evacuated fluid. The excessive formation of fibrin may also modify the findings, as a variable number of leukocytes are required to produce coagulation and still others are caught in the fibrinous masses, and it is by no means necessary that all varieties of the leukocytes should be implicated in the same proportions.

All these reasons lead the author to regard the conclusions obtained by cytodiagnosis as very deceptive, and to state that they should never be employed as the sole foundation of a diagnosis. In his opinion the establishment of rigid cytodiagnostic formulæ is as much opposed to our knowledge of general pathology as it is to the first commandment of clinical diagnosis—that we should diagnose from all the symptoms and never from a single one. Cytodiagnosis, like many other modern methods of investigation, rejoices in a loud-sounding title, which causes us to forget that it has to do only with the establishment of a single symptom, and it has consequently awakened false hopes which will never be realized. These conclusions have been forced upon the author both by his own experience and also by the contradictory results obtained by means of cytodiagnosis as they have been published.

In considering the cytologic findings obtained in the examinations of various cavity fluids, it must, therefore, be remembered that numerous exceptions to the usual types may be present. In a word, there is not a single cytologic picture of these fluids that can be regarded as pathognomonic for any one type of disease.

The Cytology of Fluids Obtained from Serous Cavities

(For the cytology of cerebrospinal fluid see p. 939.)

The main object of controversy in the literature is still the cytologic character of the exudates in so-called primary tuberculous pleurisy. Originally the predominance of lymphocytes over the polynuclear cells was looked upon as the characteristic and almost pathognomonic finding. This assertion, however, could not be accepted as it stands, because many exudates that contain lymphocytes exclusively are not tuberculous, and, on the other hand, quite a number of quite recent tuberculous exudates contain an abundant, indeed, an overwhelming, number of polynuclear cells. Königer states, however, that even in these cases the lymphocytes begin to predominate after the second week, replacing the polynuclear cells as well as the endothelial cells which, though present in large numbers early in the case, gradually disappear. Evidently, such predominance of lymphocytes depends upon the relatively benign character of the so-called primary tuberculous pleurisy. In these cases the real inflammatory phenomena disappear very quickly, and the tuberculosis, which in itself cannot be looked upon as an inflammatory process, leads to a hyperplasia of the lymphatic tissue. However, there are exceptions to this behavior of tissues if the tuberculous pleurisies are of higher virulence; in this case polynuclear cells predominate for a longer time. On the other hand, it must be admitted that exudates of a different type may present cytologic pictures similar to the tuberculous exudates, with their abundance of lymphocytes, if the infection causing them is of the same degree of virulence as in tuberculosis. The predominance of polynuclear cells for a longer period of time has been regarded as characteristic of the so-called secondary tuberculous pleurisy, that is, for such cases as develop on top of a manifest tuberculosis. The author, however, cannot grant that this differentiation is justified by the facts. Even the so-called primary tuberculous pleurisy is, of course, not primary in the real sense of the word, depending, as it does, upon the existence of tuberculous foci elsewhere in the body. A certain diagnostic importance must also be attached to the presence of red blood-cells, which are frequently, though not at all constantly, found in these fluids. However, any type of pleurisy may lead to the appearance of a hemorrhagic exudate. Königer lays special stress in diagnosis upon the character of the polynuclear cells, which, if exceptionally numerous in a tuberculous pleurisy, usually degenerate very quickly. They either shrivel, the nuclei becoming pyknotic, or they simply break up. The resulting structures are peculiar small cells which occasionally resemble the neutrophile pseudolymphocytes described on p. 792. To be sure, the neutrophile granules often disappear in this process of degeneration, and the cells may then be mistaken for lymphocytes or for nucleated red blood-cells. Fig. 3 Pl. IX, shows such pseudolymphocytes or dwarfed leukocytes that were present in abundance in a tuberculous pleural exudate. The tuberculous nature of the exudate was in this case made sure by the finding of tubercle bacilli

in the fluid. The very abundant content in endothelial cells was also quite striking in this case; they were found either discrete or in large strips and "plaques," appearing in a great variety of forms. The patient suffering with this affection was finally cured. Königer's claim that the absence of endothelial cells differentiates tuberculous exudates from transudates in nephritis and in passive congestion possessing the same cellular content so far as the lymphocytes are concerned cannot be reconciled with the findings in this remarkable case, which, until tubercle bacilli were discovered in the exudate, was supposed to be a malignant tumor of the pleura.

Similar findings characterize the exudates accompanying tuberculous peritonitis.

The exudates due to acute infections (streptococcic, staphylococcic, pneumococcic, typhoid, or rheumatic fever) usually contain, in the early stages, at least, a preponderance of polynuclear leukocytes, even when they are not frankly purulent in character. Königer thinks that it is typical for the leukocytes in these cases to degenerate by the swelling and hyaline changes of the cell-body and of the nucleus, by the appearance of vacuoles in the former and by the diminution of the chromophilic property of the protoplasm and of the nucleus. These processes differ from those occurring in the degeneration of the polynuclear cells in tuberculosis, and are thus important from the standpoint of differential diagnosis. In later stages of these affections also the polynuclear cells may be replaced by lymphocytes. In cases of pleurisy due to infarcts only polynuclear cells likewise predominate in the early stages; later they are replaced by lymphocytes.

Hydropic exudates, usually due to passive congestion or to affections of the kidneys, are characterized in general by the abundance of endothelial cells, that are cast off singly or in plates. Lymphocytes are likewise numerous, while in uncomplicated cases polynuclear leukocytes are not seen at all. Red blood-cells are found frequently in transudates due to passive congestion as well as in effusions accompanying nephritis.

When pulmonary infarctions take place or symptoms of uremia are present, polynuclear leukocytes frequently appear as well. Paracenteses may likewise lead to such secondary changes in the character of the fluids. Serous effusions accompanying neoplasms are generally characterized by their abundant content in endothelial cells. Tumor cells likewise may be present. The latter, however, are often extremely hard to differentiate from endothelial cells. Extreme degeneration, especially of fatty nature, has been claimed to be characteristic of tumor cells, yet one would be very venturesome to base a diagnosis of a tumor on this phenomenon. Occasionally, however, larger particles of tumor tissue may be found in puncture fluids. In such a case the advanced degeneration of the cells and the stratified structure of the cell groups should have some weight in the microscopic diagnosis of such particles as tumors; in other cases certain forms of cells characteristic of individual types of tumors, especially if such cells occur repeatedly in large collections, are of importance in differentiating tumor tissue from the endothelial cells that are usually roundish in form. Among such forms cylindroid cells, spindle-shaped cells, etc., may be mentioned.

A rather infrequent and peculiar phenomenon is the occurrence of many eosinophile polynuclear cells of pleuritic exudates—the so-called "pleural eosinophilia" of the French authors. Such cells may occasionally reach 75 per cent. of all the cellular elements present. On the other hand, smaller numbers of eosinophile cells, ranging from 1 to 5 per cent. of the total number, is quite a frequent finding. Up to the present time all attempts to determine the significance of well-marked eosinophilia of the pleuritic fluids have been unsuccessful. The circumstances under which these cells make their appearance are quite varied. They have been found in tuberculosis, in the exudates of polyarthritis, in pulmonary gangrene, in the presence of malignant tumors, etc., so that no pathognomonic significance can be attached to them. In such cases pleural eosinophilia is quite independent from the conditions in the blood which does not necessarily show a similar predominance of eosinophile cells at the same time.

Finally, the occasional more or less marked predominance of mast cells in pleural exudates must be mentioned; the significance of these cells, however, has been no more securely determined than that of pleural eosinophilia.

Cytology of Purulent Exudates

Only a few studies of this subject exist, apparently because suppuration is regarded as one and the same condition in every case, though it is probable that such a view is not justified. The most important problem is the differentiation of tuber-

culous purulent exudates from such as are caused by the common pyogenic organisms, staphylococci, streptococci, etc. As we have seen, the degeneration of the polynuclear cells, with their transformation into pseudolymphocytes or dwarfed leukocytes, is typical of the serous tuberculous exudation. On the other hand, in a purulent tuberculous exudate the cells usually undergo complete granular and fatty degeneration, so that in a tuberculous empyema of the pleura, for instance, after a while only nuclei and detritus are found. Finally, in an acute suppurative non-tuberculous empyema, the pus-cells are either perfectly preserved or, if the disease has lasted a long time, they degenerate in quite a different fashion. Instead of extensive degeneration, the cell and the nucleus appear simply swollen and poorly stained, just as in serous exudates of a similar nature. In general it may be said that the leukocytes of exudates due to acute infections are the better preserved the milder the affection. It may be added that tubercle bacilli are found only in the minority of cases in tuberculous pus; in most cases such pus appears to be sterile microscopically, even if it prove virulent by inoculation into animals. In other purulent processes the causative agents are usually found in the dry preparations without very much trouble.

Proteolytic Properties of Exudate Cells

H. Kolaczek and E. Müller¹ have described a method for differentiating chemically pus caused by pyogenic cocci from tuberculous pus. This method depends upon the presence of distinct proteolytic properties in pus produced by pyogenic cocci, while no such properties are to be found in tuberculous pus. These authors make use of the serum plate method described in the section on the examination of feces for ferments. (See p. 542.) Several drops of the pus that is to be examined are placed on the serum plate, which is then kept at a temperature of 50° to 60° C. The proteolytic action is shown by the liquefaction of the coagulated serum in places where the drops of pus sink into the medium and form small depressions in the plates. Müller and Kolaczek have come to the following conclusions as a result of their investigations:

1. In this test the absence of digestion of the coagulated blood-serum excludes acute suppurative conditions due to the common pyogenic organisms. According to all observations up to the present time, such a result indicates almost surely the tuberculous nature of the process in question. Even in case a very weak proteolytic action is observed, the latter process is probable.

2. Extensive and speedy digestion of the coagulated blood-serum speaks either for an infectious process, caused by the common excitants of acute pyogenic processes, or for tuberculosis plus a mixed infection with such organisms. This phenomenon, however, may also be observed in cases of pure tuberculous infection if the lesion has been previously treated by iodoform injections.

E. Müller has recently shown that the serum plate method can be replaced by a purely chemical reaction with Millon's reagent, which usually gives similar results. This reaction depends upon the ability of Millon's reagent to coagulate proteids, the coagulation being different in character if, in the one case, the pus contain true protein, or, in the other, its chief content be in albumoses resulting from the presence of proteolytic ferments. Müller gives the following description of his method of examination: "Several very small and fairly deep porcelain dishes are filled almost to the top with Millon's mercurial solution. (See p. 604, note 1.) Very different results are then obtained when a drop of thin pus free from blood, obtained from a tuberculous lesion or from one caused by the common pyogenic organisms, is added to the reagent. The drop of pus caused by the pyogenic cocci forms a spreading disc upon the surface of the reagent, while the tuberculous pus is gathered into a firm film. If an attempt be made to lift the first drop with a platinum needle or to depress it, it breaks up very easily. The tuberculous pus, on the other hand, has such a firm consistence that it can be raised out of the fluid without much difficulty, and frequently assumes a bean or pea-shaped form when depressed into the reagent. A few minutes later, or at most within half an hour, another easily noticed difference may be observed. The fluid about the tuberculous pus retains its original color, showing a great contrast to the brilliant red imparted to Millon's reagent by the pus of pyogenic cocci. In a short time the latter color changes to yellow. In both cases, however, the drops of pus that float about in the reagent assume a reddish tinge." Müller thinks that the red discoloration is caused by the presence of aromatic bodies.

¹ See Müller and Jochmann, Cong. f. inn. Med., 1907.

Müller has likewise proved that by means of the serum-plate method proteolytic properties may be shown in the blood of myeloid leukemia, in contradistinction to lymphoid leukemia, thus proving that this property depends upon the presence of myeloid cellular elements. However, the polynuclear cells contained in tuberculous pus are likewise of myeloid nature, and it is quite uncertain, therefore, what causes are responsible for the disappearance of the proteolytic action of such pus. It may be that this action is inhibited by an antiferment, or the ferment itself may have been destroyed.

E. Müller¹ has recently studied the proteolytic properties of the sediments obtained from serous exudates by centrifugation. He has found that in them the proteolytic action was likewise dependent upon the presence of polynuclear cells. The fluid itself, after being freed from the leukocytes, occasionally showed similar activity, due probably to the elements derived by the solution of cells; often, however, such fluid inhibited proteolysis by virtue of its content in antiferment. In this latter respect it was similar in action to normal blood-serum. The final action of such a fluid depends upon the relative quantities of the ferment and antiferment bodies present.

ANIMAL EXPERIMENTS WITH EXUDATES

Animal inoculations for determining the etiology of inflammatory exudates have been confined mostly to the demonstration of tuberculosis. As is well known, tubercle bacilli are found only in a small minority of serous and even purulent tuberculous exudates. This is evidently due to the fact that the bacilli reach the exudates in small numbers only, being, for the most part, retained in the serous membrane itself or in the fibrin layers formed upon it. It may be, too, that the bacilli in these cases assume the granular or split forms that are hard to recognize, or perhaps they lose their acid-fast properties. In such case, just as in the examination of sputum and urine, animal inoculations must be used for a final diagnosis. This method has shown that a great number of so-called idiopathic pleuritis, following a cold, etc., are really of tuberculous nature. However, the statistical data as to the frequency of successful animal inoculations in this type of cases vary very markedly. This is in all probability due to the different technic used by the various observers. The most important element in achieving success in such inoculations consists in the employment of a large quantity of the exudate, the necessity for this being evident from the small content of such exudates in bacilli. At least 10 cc. of the serous exudate should be used in inoculating a guinea-pig, and still better results are obtained when 20, 30, or even more cubic centimeters are used. Such large quantities of exudate may, however, have a toxic effect upon the guinea-pig, which is the only type of animal that comes into consideration in these experiments. The animals may succumb to the toxic effect before the tuberculosis has had time to develop, and, it is, therefore, best to centrifuge serous exudates and use only the sediment which contains most of the bacilli entangled in the fibrin flakes and in the clumps of leukocytes. In this manner it is possible to obtain for injection the virulent portion of 50 cc. of the exudate. For other technical points in reference to the technic of animal inoculations see p. 714, dealing with the examination of sputum.

[Despite Professor Sahli's logical objections to the clinical value of cytodagnosis, the editor inserts in the following a note which was prepared by Dr. Musgrave for the translation of the last edition:

DIAGNOSTIC VALUE OF PLEURAL FLUIDS

In recent years many investigators in Europe have done a large amount of work with reference to determining the cause of pleural effusions, and two new and valuable methods of investigation have been published.

In 1900 Widal and Ravaut published the results of their researches, based upon the differential enumeration of the white blood-corpuscles and endothelial cells found in the sediments of serous fluids, and, as a result, have formulated the following laws, or so-called cytologic formulas:

1. A predominance of lymphocytes means a tuberculous effusion.
2. A predominance of polynuclear leukocytes means an effusion of an acute infectious origin.
3. A large number of endothelial cells, occurring especially in sheets or plaques, means a mechanical effusion or transudate.

They also divide tuberculous pleurisy into two classes: the primary form,

¹ Deut. Arch. f. klin. Med., 1907, Bd. xci.

in which there are no discoverable lesions of the lungs, and the secondary form, resulting from an underlying tuberculous lung focus.

In the secondary variety the lymphocytic formula, as seen in the primary form, does not usually hold good, but, instead, the sediment is almost entirely composed of necrotic cells and detritus. Of the distinguishable cells, a large proportion

Fig. 359.—Lymphocytosis: Case of primary tuberculous pleurisy (Percy Musgrave; photographed by L. S. Brown).

may be polynuclear. This difference is probably due to a mixed infection. Of the acute infectious varieties, they note those due to the pneumococcus, streptococcus, and staphylococcus. In the pneumococcus variety they described the occurrence of considerable numbers of large cells having phagocytic properties.

Fig. 360.—Acute infectious pleurisy, showing polynuclear leukocytes and large phagocytic endothelial cells (Percy Musgrave; photographed by L. S. Brown).

In the streptococcus variety these cells are comparatively few in number, and the percentage of polynuclear leukocytes is greater.

These formulas have been extensively investigated by numerous observers, especially in France, and to a lesser extent in Germany, and have, in the main, been found correct. Certain modifications, however, must be taken into consideration.

The chief of these modifications, which has been pointed out especially by Namyn, is that lymphocytes may also predominate in transudates of long standing or near the end of an acute infectious case where the process is subsiding or where the infection is a very mild one. The specific gravity and the amount of albumin aid us in eliminating the first mentioned of these conditions, and the clinical evidence usually gives a clue to the nature of the process in the second. Both of these conditions are rarely met.

In the first week or ten days of a tuberculous effusion polynuclear elements may predominate, but these rapidly disappear and give place to a purely lymphocytic formula.

The phagocytic cells mentioned above as occurring especially in the cases of pneumococcus origin are of very large diameter as compared with the other elements occurring in the sediment, and the writer has frequently found that they measure as much as $20\ \mu$. These cells frequently contain partly digested polynuclear and other cellular elements, which can easily be seen included in their protoplasm. Their occurrence in large or increasing numbers is usually a good prognostic sign; and their absence, together with the presence of bacteria, is usually a warning of approaching empyema. From the observations which the writer has been able to make, the presence of polynuclears in a proportion of over 90 per

Fig. 361.—Endothelial cells from a pleural transudate due to cardiac disease (Percy Musgrave; photographed by L. S. Brown).

cent., and the presence of bacteria in most cases, precedes an empyema by only a few days.

Little need be said of the formula for the transudates except that the diagnosis is occasionally complicated by the presence of a considerable amount of blood, which raises the specific gravity and the amount of albumin. This blood is usually accidental.

In addition to these three classes of fluids we have the cancerous cases. These are difficult to diagnose, since the majority of pathologists agree, the writer thinks, in saying that it is difficult to differentiate the so-called cancer cells from endothelium, unless actual pieces of the cancerous tissue can be isolated. The iodine reaction (showing glycogenic degeneration) was thought at one time to be suggestive of the cancer cells, but this reaction is very commonly seen in the endothelial cells of simple transudates and in other conditions where endothelium is found.

The few cases of cancer that the writer has been able to study have shown a high specific gravity, 1018 or over, and an albumin content of over 1.5 per cent. The sediment has shown many more endothelial cells than are found in the tuberculous cases, and these cells are often found in plaques, which is very rare in tuberculosis. There is usually a much larger number of lymphocytes proportionally than in the simple transudates.

In addition to the above method of investigating pleural fluids, to which the writers have given the name cytodiagnosis, Jousset has published a new procedure for the detection of tubercle bacilli in these fluids, to which he has given the name of inoscopy, and which is of value in some cases.

The technic of cytodiagnosis is as follows: The fluid should be drawn with the usual aseptic precautions into sterilized flasks or tubes. If it is already clotted when received for examination, it should be shaken and stirred with a glass rod until the clot is thoroughly contracted, and the clot, or all clots of large size, should be removed. This is necessary because some of the cellular elements are entangled in the fibrinous meshes, and by contraction of the clot are set free. Widal and Ravaut accomplished the process of defibrination by placing sterilized glass pearls in the flask and shaking the fluid thoroughly. This the writer does not believe is essential for an accurate differential estimate of the cellular elements. The fluid is then placed in centrifuge tubes and centrifugalized for five minutes, at least. The supernatant fluid is decanted gently at first, and when only a small amount remains, the tube is inverted for a few seconds. A few drops will adhere to the side. The sediment is stirred thoroughly with a small platinum loop, the sides of the glass being rubbed to remove adherent portions. When the sediment is thoroughly mixed with the few drops of fluid remaining after decantation, a drop of the mixture is removed with the platinum loop, and a cover-slip smear made. This is allowed to dry spontaneously or by gently heating the preparation. (Heating to the boiling-point will spoil it.)

Many methods of fixing and staining these preparations have been used by the various investigators. Alcohol, ether, chloroform vapor, and osmic acid have been used as fixative agents. Ehrlich's triple stain, hematoxylin and eosin, methylene-blue and eosin, Löffler's blue, and a great variety of other stains have been employed. Some writers have maintained that careful differential staining is not necessary, but from the writer's observations he cannot agree with them, for the reason that careful differential staining of the protoplasm and granules of the polynuclear elements is essential, since the nuclei of these elements are often globular when the cell is degenerated, and they may be mistaken for lymphocytes.

The method of staining which has given the best results in the hands of the writer is practised as follows:

Cover the preparation with a staining fluid composed of:

Wright's blood-stain.....	3 parts
Pure methyl-alcohol	1 part.

Allow this mixture to remain on the preparation twenty to forty-five seconds, then dilute it with 8 or 10 drops of water, and allow it to stand one to two minutes. Wash very gently, preferably by flooding the slide with a dropper. Do this four or five times, allowing the water to remain on the slide a few seconds each time. Vigorous or forcible washing will destroy the film and spoil the preparation. Dry the preparation by holding it between the thumb and forefinger and waving it through the Bunsen or alcohol flame. Do not attempt to blot the preparation or heat it above the temperature which the fingers will bear. Mount in xylol balsam and examine with an oil-immersion lens.

Inoscopy is practised as follows:

1. The fluid should be drawn with aseptic precautions into sterilized flasks (Erlenmeyer flasks preferably). At least 100 cc. should be taken, although results may sometimes be obtained with much smaller amounts. Allow the fluid thus taken to clot.

2. Shake the fluid gently to contract the clot as much as possible and then wash it, on a piece of sterile linen or fine gauze wrapped over the end of a funnel, until all serum is washed away.

3. Remove the clot or clots with a sterile spatula, and place them in a small flask with sufficient of the following fluid to digest them:

Pepsin.....	2 gm.
Pure glycerin,	
Strong HCl.....	of each 10 cc.
Sodium fluorid.....	3 gm.
Distilled water.....	2000 cc.

The necessary amount of this fluid will vary, of course, with the size of the clot to be digested, but in most cases 20 or 30 cc. are sufficient. A freshly prepared pepsin (HCl solution) apparently serves as well as the above fluid, but will not keep on standing as the above fluid does.

4. Place the above preparation in the incubator or oven until the clot is digested. A temperature of 37° C. for two or three hours will suffice, but the time is shortened if it is kept at a temperature of 50° C.

5. When the clot has disappeared, pour the mixture into centrifuge tubes and centrifugalize for five to ten minutes. Decant the supernatant fluid as described under Cytodiagnosis.

6. Make a cover-slip preparation and stain it for tubercle bacilli. Care, however, should be taken not to decolorize too long—one-half to three-quarters of a minute with Gabbett's solution is sufficient. Dry and mount.

The majority of the bacilli found by this method are shorter and broader, as a rule, than the tubercle bacilli usually seen in sputum, and some are paler red, but all forms occur. These bacilli may occur singly or in groups. The largest part of the sediment consists of undigested nuclei and a small amount of detritus.

Observations¹ made by the writer at the laboratory of the Massachusetts General Hospital on 72 cases examined with reference to physical properties, albumin, animal inoculation, inoscopy, and cytodiagnosis resulted as follows: 51 cases were classed as tuberculous; 46 of these were classified as primary and 5 as secondary (bacilli in the sputum). Of the 46 secondary cases, 50 per cent. (23 cases) were proved tuberculous by one or more tests, viz., guinea-pig inoculation, inoscopy, or operation. Animal inoculation was positive in 15 cases (32 per cent.), and inoscopy in 10 out of 22 cases examined by this method. One case was proved at operation. In 5 of the 23 unproved cases the examination of the fluid probably led to faulty conclusions. There were 12 acute infectious cases, all showing a predominance of polynuclear leukocytes. Six followed pneumonia, 1 infection of the lung, 3 started from unknown sources, 1 from trauma, and 1 from abscess of the liver. There were 5 cases of simple transudate: 4 due to cardiac disease and 1 to nephritis. There were 3 cancerous cases: 2 positive and 1 doubtful, all following cancer of the breast.

As a result of the study of this subject the writer thinks that we are justified in coming to the conclusion that routine and systematic examination of pleural fluids will aid us greatly in diagnosis and in determining the etiology of pleurisy. Of the methods of which he has spoken, cytodiagnosis is the only one which can easily be employed clinically. Animal inoculation, inoscopy, and culture methods can be employed only in the laboratory. Cytodiagnosis is not accurate in every case any more than any other clinical method, but the writer thinks he is justified in saying that it is sufficiently accurate, especially when taken in conjunction with the history and bedside examination, to justify its use as a routine procedure. In some cases it has not only been of more than probable diagnostic value, but has given us positive and signal results. Routine examination of pleural fluids will not only enable us to study the question of pleurisy with effusion with reference to etiology and diagnosis, but will establish a basis upon which accurate prognostic statistics can subsequently be based.—Percy Musgrave.]

OSMOTIC PRESSURE OF FLUIDS OBTAINED BY PUNCTURE

The osmotic pressure of these fluids is obtained in a manner similar to that employed for the blood. (See pp. 662 et seq. and 845.) This method of study has not yielded practical results. Ketly and Torday² state that exudates and transudates cannot be differentiated by variations in their osmotic pressure. It may be said, however, that the lower the osmotic pressure of an exudate or transudate as compared with that of the blood, the greater is the likelihood of the speedy absorption of the fluid. In reference to the freezing-points of these pathologic fluids, it may be stated that they are exceedingly variable, and may be far above or below that of the blood. This is due not only to the initial differences in the character of the particular fluids, but also to the different stages of osmotic interchange at which they are examined.

DETAILS OF EXPLORATORY PUNCTURES IN DIFFERENT DISEASES

EXPLORATORY PUNCTURES OF THE PLEURA

The most important rule for exploratory as well as for therapeutic puncture of the pleural cavity is to avoid introducing the needle too near the upper or too near the lower border of the fluid. If we puncture too low, the needle frequently only goes through both layers, bounding the pleural complementary sinus, these being stuck together with fibrin. If we puncture too high, we are apt to penetrate the

¹ Trans. Mass. Med. Soc., 1904.

² Arch. f. klin. Med., vol. lxxix.

compressed lung, for the latter often causes a dulness above the level of the fluid. Naturally, there are no generally applicable rules for the place of exploratory puncture, but we must follow the results of physical examination and puncture at a point where we find decided dulness, diminished or bronchial breathing, and diminished fremitus. Generally speaking, however, in typical pleural exudations we select the fifth or sixth intercostal space in the anterior axillary line, or else the area just below the angle of the scapula. In a test puncture of the pleura it is especially important to palpate carefully by moving the needle up and down, and so determine by its mobility whether it has penetrated a large cavity, in order that we may be enabled to select the best spot for a therapeutic puncture or for the drainage of a pleural empyema, and so avoid penetrating the lung or the diaphragm. (See the following in regard to the distinction between pleural empyema and pulmonary abscess.)

The diagnosis of pneumothorax, supported by the results of a physical examination, can sometimes be corroborated by an exploratory puncture. But the aspiration of air is not the only finding to be considered in this case, for air may be obtained not only from the pneumothorax, but also from a bronchus. On the other hand, the complete mobility of the needle in the air space ("palpatory puncture") is the determining factor in the diagnosis of a pneumothorax, whereas the aspiration of air mixed with a mucous secretion shows that the cannula has entered the lumen of a bronchus.

Intrapleural Pressure and Its Measurement in Pleural Exudates and in Pneumothorax

The pressure of a pleural exudate is determined by connecting the cannula used in the exploratory puncture with a water manometer; it is still easier and simpler to use the tube which connects the cannula with the apparatus for the reception of the exudate as a manometer by raising its open end, after it has been filled with the exudate, until the fluid ceases to escape from it. Then the height of the tube above the level of the puncture is measured in centimeters. If the end of the tube must be depressed below the puncture hole to allow the exudate to escape, the figures obtained indicate negative pressure; if it must be raised above it, the figures indicate the positive pressure existing in the pleural cavity.

The pressure of a pleural exudate depends upon two factors, one being the hydrostatic pressure of the column of fluid reaching from the opening of the cannula to the upper level of the fluid, the other the tension exercised upon the fluid by the tissues surrounding it. If D stand for the total pressure, h for the hydrostatic pressure at the level of the cannula, and s for the tension exercised by the tissues containing the exudate, then

$$D = h + s.$$

If the mechanical relations existing in the pleural exudates are to be analyzed, the values h and s can with ease be estimated separately. The hydrostatic pressure by the definition is equal to a column of fluid of the same height as the distance from the site of the puncture to the highest level of the fluid. This distance can be estimated directly in centimeters from the data of the physical examination. As only slight differences exist between the specific gravity of the various exudates and that of water, the figures obtained give accurately enough the hydrostatic pressure measured in terms of a column of water. If, now, this value be subtracted from the total pressure obtained manometrically at the site of the puncture, the tension pressure, which may be positive or negative, is obtained. The tension pressure may likewise be measured directly by determining how far the level of the fluid in the ascending branch of the manometer rises above or sinks below the level of the fluid in the thorax, as determined by the physical examination. It is to be remembered that the level of the puncture is not used in this determination. If the aspirating tube be used instead of the manometer, the level which its open end must reach just to allow the escape of the fluid is used as the point of measurement. If the level of the mouth of the tube or of the fluid in the manometer be above the level of the fluid in the thorax, the tension pressure is positive; if it does not reach that level that element of the total pressure is negative. Both methods, of course, depend upon one and the same principle, as will be seen from a graphic representation of the above equation, and their results agree with each other. D. Gerhardt used the latter method, while the same values are determined in the author's clinic by means of subtracting the value for the pressure of fluid from the general pressure as explained above.

D. Gerhardt¹ has properly called attention to the fact that the usual statements concerning the positive pressure of pleural exudates have reference only to the total pressure. If the tension pressure alone, *i. e.*, the total pressure minus the hydrostatic pressure of the fluid, be considered, it is found to be, in the majority of cases, a negative quantity, even when a recent large exudate causing marked dyspnea is present. The figures for negative pressure obtained in these cases range, according to Gerhardt, from -2 to -20 cm. of water. This phenomenon is in part explained by the compression of the lung through the increasing exudate if the former has not been rendered incompressible by adhesions or by infiltration. This factor, however, explains only why the pressure in question does not necessarily overcome atmospheric pressure, that is, is not necessarily a positive quantity. The negative figures obtained for the tension pressure, on the other hand, are explained by Gerhardt's experiments. He found that when the pleural cavities of a dog were being gradually filled with an increasing quantity of fluid, the tension pressure after a temporary rise rapidly sank to the normal negative values; it became permanently positive only in the presence of large amounts of fluid, which led to urgent dyspnea, rapidly terminating in death if relief were not given. Gerhardt explains these findings by assuming that with the increase of fluid in the pleural cavity the animal, urged on by the stimulus of suffocation, expands its thorax more and more, tending to hold it in the position of inspiration. He thinks that the same thing occurs in the formation of a pleural exudate, so that in spite of the dyspnea or, as Gerhardt puts it, because of the dyspnea, not only the tension pressure, but even the total pressure, may remain negative, however large the amount of the fluid in the pleural cavity may be. This useful drop in the pressure is produced by the increase in the capacity of the sound side of the chest, with its increased respiratory excursions, as well as by the expansion of the affected side. The marked expansion of the healthy side of the chest accounts for the dislocation of the heart, even if negative pressure accompany the presence of the exudate, because the diminution in pressure produced by the marked respiratory movements of the healthy side may often be greater than in the affected pleural cavity. Of course, the displacement of the heart is likewise favored by the positive element of pressure, the hydrostatic factor, which exists only on the affected side of the chest. It is this negative total pressure of exudates that makes simple puncture of the pleural cavity without the use of an aspirating apparatus dangerous. The danger, which the author has often pointed out in his clinical lectures, may be present even in the case of recent large exudates. The puncture hole may give access to air, which rushes in because of the negative pressure, and an artificial pneumothorax be thus produced. This accident is especially liable to happen if a high intercostal space be selected for the exploratory puncture, so that the diaphragm may be surely avoided. At such levels the positive element of the pressure, the hydrostatic effect of the column of fluid, is less apt to overcome the negative element, the tension pressure of the tissues containing the exudate. It must not be forgotten, either, that even if the total pressure be positive in the expiratory phase, it must of necessity always become negative in the inspiratory phase, if the lung be not at a complete standstill because of the exudate; otherwise no breathing is possible. Hence the well-known but occasionally neglected rule, always to precede an exploratory puncture of the pleural cavity by setting the aspirating apparatus at work and continuing suction at least until the tube for the escape of the fluid has become completely filled. After the latter has been accomplished, the suction may be stopped, if care be taken not to raise the mouth of the tube, which now acts as a siphon, any higher than the level at which the fluid still escapes from the pleural cavity.

Of course, the circumstances which favor the formation of a negative pressure in the presence of a pleural exudate are modified if, instead of soft and elastic walls, the space containing the exudate be inclosed by firm adhesions, or if the lung has become inelastic because of infiltration. In such a case even a moderate exudate may lead to the formation of positive pressure as high as its uppermost level. But this is simply a local phenomenon, while the intrathoracic pressure beyond the limits of the exudate may not be affected at all or may sink because of the effects of dyspnea, as Gerhardt has shown. The presence of a localized positive pressure need not, of course, interfere at all with the respiratory function of the affected side of the chest, even though this pressure remain positive during the inspiratory phase.

Of course, a different condition of affairs is present in an open pneumothorax,

¹ D. Gerhardt, *Deut. Arch. f. exp. Path. u. Pharm., Schmiedeberg Festschrift*, 1908; D. Gerhardt, *Zeit. f. klin. Med.*, vol. lv.

in which case high pressure values, rising to 5 or 6 cm. in terms of a column of water, are formed during the inspiratory phase, additional air being aspirated through the perforation so long as the pressure in the cavity continues to be diminished by the mechanical effects of dyspnea, as explained by Gerhardt. After a few inspirations the pressure in these cases at the height of the inspiration becomes not less than the external atmospheric pressure, and remains positive throughout the rest of the respiratory cycle. The pressure, in other words, oscillates between zero in the inspiration and the positive values named above during expiration, being thus almost constantly positive. This explains the intense dyspnea from which patients afflicted with this type of pneumothorax suffer early in the disease, before any accommodation to the changed condition has taken place. Of course, the fact that the patient is yet able to live and breathe in the presence of an intrapleural pressure oscillating between zero and high positive values is explained only by the compensating increase in the respiratory excursions of the healthy side, in which negative pressure is maintained by increased expansion of the thorax, in spite of the displacement of the mediastinal contents in that direction.

As soon as the perforation accompanying an open pneumothorax is closed, the conditions resemble those existing in the case of a pleural exudate. If fluid be present in addition to the air, the tension pressure must here likewise be distinguished from the hydrostatic pressure of the fluid.

When a fluid effusion appears in an open pneumothorax, the tension pressure may become positive in the inspiratory phase, while the total pressure may be positive throughout the respiratory cycle; however, these conditions, which, of course, exclude all respiratory function on the diseased side, need not exist on the unaffected side of the thorax.

The peculiar conditions of pressure that exist with a recently formed open pneumothorax not only lead to extreme dyspnea, dangerous to life, but must also be considered from the therapeutic standpoint. Unverricht has proposed to treat these patients by establishing communication between the affected side of the chest and the external air, thus converting the condition into a completely open pneumothorax. This proposal seems reasonable at first sight, because the operation does away with any excess of pressure over atmospheric pressure in the pleural cavity. The author, however, has had experience in one such case, which he converted into a completely open pneumothorax by inserting a large drainage-tube through the chest-wall, thus establishing free communication with the external air. The results showed that the circumstances were not at all so simple as imagined by Unverricht, for the condition of the patient became much more serious immediately after this procedure. In fact, the danger of a complete pneumothorax has been recognized generally by the surgeons and is illustrated by their disinclination to operate through the pleural cavity in affections of the esophagus or of the lungs. It was to avoid the danger of causing a pneumothorax that Sauerbruch's positive pressure cabinet and Bauer's negative pressure technic were devised. In the case mentioned above the condition of the patient was again somewhat improved as soon as the previous state of affairs was reestablished by shutting off the lumen of the drainage-tube by means of a pinch cock. It was then noticed that the patient could breathe to the best advantage when the communication with the external air was moderately reduced, dyspnea becoming greater as soon as the tube was completely open or shut. Indeed, if the tube was opened to its full extent, the patient seemed to be threatened with immediate death by suffocation. However paradoxical it may seem, yet the expiratory rise of pressure which could be brought on by narrowing the lumen of the tube in the above case, and which normally forms in an open pneumothorax contains a favorable as well as a dangerous element. This is probably explained by the fact that the chief danger of the completely open pneumothorax consists in the tendency of the air inspired by the healthy lung to oscillate between the healthy and the affected side. The unaffected lung, instead of obtaining fresh supplies of air through the trachea, is filled with the air which is partially vitiated by the respiratory exchange taking place in the affected lung, that is, with the "oscillating air," as Brauer has termed it. During expiration the healthy lung pumps part of its own vitiated air into the lung of the affected side, and receives some of it back again with the next inspiration. In addition, it is probable that, by narrowing the communication with the external air to a certain degree, as is done by diminishing the lumen of the tube passed through the perforation, it is possible to hit upon a point which enables the affected lung to participate to a certain extent in the respiratory function. This is the case when the opening in the tube and the valve-like opening in the lung are of such a degree as to result in a certain expansion of the lung in inspiration; while the fact that the air in the pleural cavity does

not immediately escape through the tube in the expiratory phase enables it to exercise a certain pressure upon the lung, and thus help in expelling some of the air from it.

The author's rule, therefore, in case he has to deal with a recent open pneumothorax of the type discussed above, is not to open the pleural cavity completely to the external air, but to puncture the pleural sac by means of a trocar provided with a stop-cock, and then to regulate the entrance of air until the best possible extent of respiratory function is established in the affected lung. So far as the practitioner is concerned, the best instrument for use in emergency is the trocar that usually accompanies Potain's apparatus for the exploratory puncture of the pleura, the lateral opening of the trocar which usually serves for the escape of fluid being previously closed. Another procedure is to introduce a drainage-tube, such as is used in Bulau's method of draining the pleural cavity, and then to regulate the size of the lumen by means of a pinch-cock fastened to the tube, until the most favorable conditions for carrying on the respiration have been established. Instead of using the pinch-cock, the degree of communication with the external air may be regulated by plunging the open end of the tube into a vessel filled with some liquid, the amount of interference with the free communication of the pleural cavity with the atmosphere depending upon the depth to which the tube is plunged into the liquid. In the author's opinion, the best procedure is to use the trocar, which has advantages over the use of the drainage-tube because the instrument may be reintroduced every other day in a new spot where better conditions for effectual respiration may be procured; the drainage-tube, on the other hand, may become loosened by the accumulation of pus about it, and thus be no longer air-tight, so that regulation of the degree of interference with the escape of air is no longer possible. It is impossible, of course, to change the tube from one place to another, because it leaves behind it a widely open perforation which does away with all possibility of affecting the pressure conditions inside the pleural cavity.

The occurrence of sudden death in the presence of pleuritic exudates, aside from the possible hydrostatic pressure upon the heart and the great vessels, especially the veins, caused by the movements of the patient, is thought by Gerhardt to be due to sudden failure of the inspiratory forces. Of course, in cases of very extensive exudate, which may have at first become compensated for by the expansion of the affected side of the thorax, thus mechanically producing negative tension pressure or even a negative total pressure, there may thus suddenly arise a high positive pressure involving the lungs of both the affected and the healthy side, as well as the heart and great vessels. Such pressure, of course, is quite incompatible with the continuance of life.

EXPLORATORY PUNCTURES TO DEMONSTRATE PULMONARY CAVITIES

In addition to physical signs, it is sometimes very desirable, especially for deciding upon an operative procedure, to make use of exploratory punctures, in order to demonstrate pulmonary cavities (tuberculous cavities, bronchiectases, and abscess cavities) and to determine their exact position and size. This naturally succeeds only when the cavities are filled with purulent exudate. It is, therefore, advisable to undertake the puncture at a time when the patient has not expectorated for a long period. Since a small quantity of purulent material may be obtained from a bronchus in bronchial catarrh, it is important to withdraw as large amounts of pus as possible, and to determine by slight movements of the needle whether the latter has penetrated a large cavity, an attempt that will succeed only when the cavities are situated superficially. The contents of pulmonary cavities are usually offensive in odor; for this reason the determination of the odor of the material withdrawn by the puncture, and its identification with the odor of the sputum, are sometimes of considerable significance.

Quite as important a question, in cases where we have determined the existence of a cavity, is whether the cavity is really situated within the lung or is part of an empyema, the indications for operative interference often depending upon such a distinction. The depth from which the pus is withdrawn will often be an important consideration in settling this question. We determine this depth by successive aspirations, pushing the needle little by little back and forth. The characteristics of the pus may also sometimes be employed for determining the position of the accumulation; if it be rather slimy, it is probably partly derived from an intrapulmonary cavity, which is still lined with mucous membrane (bronchiectasis). It may also be noted that the pus of abscess cavities and tuberculous cavities is not

slimy. A mixture of air and pus argues in favor of an intrapulmonary cavity and against an empyema, provided, of course, that the physical signs of a pneumothorax are absent and that we are sure that the syringe is air-tight. The air must also be withdrawn at the same time and from the same depths as the pus, and the amount of the withdrawn pus must prove the existence of a pathological cavity. If this be not the case, we must always consider the possibility that the air and purulent material come from a bronchus. The microscopic examination of the purulent fluid furnishes certain data about the nature of the cavity. Such an examination is performed like a sputum examination (elastic fibers, tubercle bacilli, and other bacteria, crystals, etc.). (See p. 703 et seq.) The presence of elastic fibers argues especially against empyema, and in favor of a destructive pulmonary lesion, *i. e.*, cavity formation.

EXPLORATORY PUNCTURE OF THE PERICARDIUM

In exploratory puncture of the pericardium, injury to the heart is best avoided by introducing the cannula almost in the sagittal plane, and directed but slightly toward the median line. The puncture should be made at the left border of the cardiac dulness and to the outer side of the apex-beat, in case the latter be present. The pleura is not considered because no untoward result occurs if it be punctured,

even in case no adhesions have formed between its costal and pericardial surfaces. According to Döbert,¹ however, there are cases in which a puncture in this location gives a negative result, and in which the fluid may be more easily reached through the fourth intercostal space to the right of the sternum. The only cases in which this procedure is applicable are those in which there is a very pronounced and un-

Parietal surface of the peri-
cardium

Heart
Pericardial exudate

Fig. 363.—Transverse section of a pericardial exudate (Curschmann)

doubted pericardial widening of the cardiac dulness toward the right. In this situation the right ventricle and auricle are uncomfortably close, and their thin walls might easily be injured by the cannula. Paracentesis of the pericardium is much less risky if the sac be punctured from the left side, and this should be looked upon as the procedure of choice. Yet even in this situation no point can be named

¹ Berlin. klin. Woch., 1904, No. 18.

that is suited for paracentesis in all cases. The needle is best introduced in the sagittal direction at the most external limit of the superficial dullness. The choice of the intercostal space should depend upon the height of the diaphragm, in cases normal in this respect the exudate is best reached through the fifth space; if the diaphragm be low, on the other hand, the sixth space should be chosen. The cannula must be cautiously introduced, and the introduction must be suspended at the moment when resistance is no longer encountered or the heart is felt beating against the instrument. Since the danger of injuring a coronary artery or the heart itself (tearing of the thin-walled portions of the heart upon the cannula, Kronecker's "coördination center") is not to be despised and cannot certainly be avoided, the author does not advocate exploratory puncture of the pericardium for purely diagnostic purposes. He believes it should be employed chiefly in those cases of large pericardial exudate in which there is an urgent indication for the removal of the fluid, and then a point must be selected at which the cannula may readily enter the

Parietal surface of the pericardium

pericardial cavity. Figs. 362 to 364 show the topographic relations of a large pericardial effusion. The reader should also consult the work of A. Calvert (Johns Hopkins Hospital Bulletin, 1907, vol. xviii, 199), which gives original pictures of cross-sections of cadavers and reproduces the well-known cross-sections obtained by Pirogoff from a cadaver with a pericardial exudate.

EXPLORATORY PUNCTURE OF INTRATHORACIC AND ABDOMINAL TUMORS AND CYSTS

Both in solid tumors and in those with fluid contents exploratory puncture will afford useful data—in the one case by the demonstration of characteristic morphologic tumor elements, and in the other case by the demonstration of fluid which can be accurately examined.

So far as the technical details are concerned, it is almost always a good rule to puncture a tumor only in those places where it lies superficially according to palpation and percussion. It is not wise to puncture through the intestine, although experience has shown that such a puncture with a very fine needle will probably not cause any damage. (See p. 911.)

The diagnostic value of exploratory punctures in *intrathoracic tumors* was well shown in a case of lung tumor at the Bern Clinic. Abundant myelin bodies were found in the fluid withdrawn. They showed in this case even more bizarre shapes than are found in the sputum. (See Fig. 365.) Dr. Zollikoffer proved that these myelin bodies, like those of the sputum, consisted chiefly of protagon (Fig. 276, g). The microscopic examination of the tumor showed that these bodies were situated exclusively in the remaining bronchi and alveoli. Their large amount should perhaps be attributed to the stagnation of the secretion associated with the tumor formation. Zollikoffer obtained similar results in studying anatomic preparations of pneumonia and tuberculosis. The appearance is, therefore, not pathognomonic of pulmonary tumors, although in none of the last mentioned cases was there such an abundance of the myelin bodies as in the pulmonary tumors. The author considers that their presence in the fluid withdrawn by puncture shows surely that the needle

has entered the lung, which is significant in diagnosing the site of intrathoracic tumors, and in distinguishing pleural thickenings from pulmonary consolidations and pulmonary tumors.

Only very fine needles should be employed to puncture cystic abdominal tumors, because, if no adhesions be formed, the fluid may trickle into the peritoneal cavity, and, if infectious, produce serious consequences.

To prove that a cystic tumor is the gall-bladder, it is necessary to determine constituents of the bile in the fluid withdrawn (the bile-tinge to the color, the chemical determination of biliary pigment (p. 575 et seq.), the microscopic demonstration of cholesterol crystals (Fig. 278, b). But it must be emphasized that an occluded gall-bladder frequently contains no biliary constituents, cholesterol persisting the longest of any of them. If the aspirating needle strike against hard masses, gall-stones would be strongly suggested.

In the fluid aspirated from echinococcus cysts the microscopic demonstration of *echinococcus scolices*, daughter cysts, and remnants of the laminated membranes (see Fig. 271) is of diagnostic importance. (See the plates in Küchenmeister and Zürn's *Die Parasiten des Menschen*, 2d ed., Pl. III.) In favorable cases we can sometimes obtain from the fluid in multilocular cysts both scolices and hooks, although, on account of the small size of the bladders, the fluid can be obtained only in traces. However, in this case we should not necessarily expect a positive result, because the majority of the cysts in multilocular type are sterile. Provided the

Fig. 365.—Myelin kernels (protagon) obtained by exploratory puncture from a tumor of the lung.

cortex or investing membrane is not inflamed, the echinococcus fluid is chemically characterized by the absence of proteid content and the presence of succinic acid. (For demonstration see below.)

The thickness of the fluid, i. e., its viscosity—is characteristic of ovarian cysts as contrasted with parovarian cysts. Oftentimes this cannot be demonstrated in the fluid withdrawn with a very fine needle; in such cases the chemical demonstration of paralbumin proteid is in itself sufficiently characteristic.

The presence of pancreatic ferment in the fluid withdrawn is suggestive of a pancreatic cyst. (See below.) In this connection H. Zeehuisen¹ came to the following conclusions: A positive test for trypsin in the fluid supports the diagnosis of a pancreatic cyst very decidedly, as does the demonstration of a fat-splitting ferment. Negative findings in both instances do not, however, argue with certainty against pancreatic cysts. Diastatic action is useless for the diagnosis, as all sorts of fluids withdrawn possess this peculiarity. The occurrence of tyrosin and leucin crystals in pancreatic cysts is of diagnostic interest (Figs. 278, c, 240 and 241).

Hydronephroses and other cysts which are connected with the urinary tract are oftentimes characterized by a considerable urea content.² (See below.) However, if the cyst has been shut off for any length of time, urea may be absent. Other fluids of the body, such as blood or serous exudates, contain but little urea except in cases of uremia.

¹ Centralbl. f. inn. Med., 1896, vol. xl, p. 1017.

² Traces of urea also occur in exudates and transudates.

Demonstration of Succinic Acid in Echinococcus Fluid.—Hoppe-Seyler¹ describes a method of demonstrating succinic acid in the blood, also applicable to echinococcus fluid. The method is as follows: After the fluid has been carefully acidified with hydrochloric acid, it is freed from albumin by boiling. This is necessary only when the fluid comes from inflamed echinococcus sacs, because ordinarily echinococcus fluid is free from albumin. The clear filtrate is neutralized as exactly as possible with caustic potash, concentrated over a water-bath until it is somewhat thickened, completely precipitated with absolute alcohol, and filtered after cooling (alkaline salts of succinic acid are insoluble in alcohol). The precipitate dissolved in water, filtered, and evaporated may show crystals of alkaline salts of succinic acid. The succinic acid may be dissolved out of the concentrated aqueous solution by shaking the latter with a mixture of equal parts of alcohol and ether acidified with hydrochloric acid, and pure crystals may be obtained by evaporating the filtrate from this solution. Salkowski² mentions the following peculiarities of succinic acid for the purpose of identification: It forms four-sided needles, its melting-point is 182° C., it is readily soluble in water, much less so in alcohol, and difficultly soluble in ether. If heated in an ignition tube, the acid melts and sublimes, being partly changed to anhydrous succinic acid. When heated on platinum, the acid volatilizes and forms irritating vapors. If neutral lead acetate be added to the aqueous solution, lead succinate, a heavy crystalline precipitate, appears.

Demonstration of Paralbumin (Pseudomucin in Ovarian Cysts).—Salkowski gives the following rules: 1. A few drops of alcoholic solution of rosolic acid are added to a small quantity (about 25 cc.) of the fluid; the mixture is heated to boiling, and decinormal sulphuric acid is added drop by drop until a yellowish tinge indicates that the reaction of the fluid is acid. The solution is again heated to boiling and filtered. If paralbumin be present, the filtrate is cloudy. 2. The same quantity of the cyst fluid is precipitated with three times its volume of 95 per cent. alcohol and filtered. The precipitate is washed several times with alcohol, dried between sheets of filter-paper, and then shaken up in a mixture of one volume of hydrochloric acid and three volumes of water. The tube is then heated over a wire net to boiling, allowed to cool, and Trommer's test (p. 587) performed with a portion of unfiltered fluid. After boiling, a specimen is cooled off by placing the test-tube in water. Should paralbumin or mucin be present, a precipitate of red copper oxid will form. In differentiating paralbumin (pseudomucin) from mucin, it should be remembered that the former cannot be precipitated from the cyst fluid by means of the acetic acid.

Salkowski's Test for Urea in Cysts of the Urinary Tract.—One hundred cc. of the fluid are exactly neutralized with acetic acid and then poured into 400 cc. of 95 per cent. or absolute alcohol. After it has been shaken and stirred and has stood for twenty-four hours, it is filtered, the coagulum is washed off with alcohol, and the extract evaporated over a low flame. The residue is treated several times with absolute alcohol, and the extract evaporated to dryness. A few drops of nitric acid are added to the residue, after it has cooled off, and it is then allowed to stand in a cool place for twenty-four hours. As a general thing, the nitric acid produces only a cloudiness at first, due to the fatty acids derived from the soaps which are almost always present. Little by little nitrate of urea is thrown down as a crystalline precipitate. This is characterized by the shape of the crystal (Fig. 13), and also by the fact that when the water is drawn off with filter-paper, and the crystal heated, it decomposes energetically or undergoes sudden combustion. No residue may be left, and if present, it being in the melted state, is difficult to see. Should a residue once found give an alkaline reaction when a drop of water is added to it, sodium nitrate is present, in which case the sudden combustion does not signify the presence of urea. Provided the quantity of nitrate of urea is sufficient, it may be identified by the following reactions:

1. Nitrous acid decomposes urea or urea nitrate into nitrogen and carbon dioxid with ebullition of gas.
2. Potassium bromid does the same (p. 630).
3. If urea or urea nitrate be boiled with NaOH or KOH, ammonia is liberated.
4. A neutral (or nearly neutral) solution of mercuric nitrate causes a precipitate even in very dilute solutions of urea or urea nitrate.
5. If urea or urea nitrate be decomposed with furfurol and concentrated HCl, a purple color is developed after a few minutes.

Demonstration of Pancreatic Ferments in Pancreatic Cysts.—For the demonstration of the tryptic, diastatic, and fat-splitting actions of fluid obtained by puncture see pp. 509 and 513.

PUNCTURE OF THE SPLEEN

Puncture of the spleen, such as is recommended in typhoid in order to demonstrate typhoid bacilli microscopically in the material obtained and by means of culture, is not without danger. The small wound in the spleen in itself is of no particular importance, but the capsule may be considerably torn by the respiratory excursions, as has been shown repeatedly at autopsy. This has often led to severe hemorrhage and symptoms of peritonitis. The author warns against puncture of the spleen, especially since we have at the present time in Widal's serum test a method much more simple and far less dangerous. In any case, care should be taken to perform the puncture rapidly and to see that the patient does not breathe during the act. [Puncture of the spleen in obscure cases of estivo-autumnal malaria is still recommended by some writers.—Ed.]

EXPLORATORY PUNCTURE IN APPENDICITIS

This method in suitable cases is devoid of danger and may be of practical value. It is self-evident that it cannot be applied in cases of diffuse resistance, especially when this is deep and when intestines intervene. There is little chance in these cases of obtaining pus, so that the procedure would be useless, to say the least, if not dangerous. When, however, there is a well-defined tumor over which the percussion-note is dull, an exploratory puncture may be performed without danger. Under these conditions one is sure to pass through already infected tissue, so that the risk of infection is unimportant. One may in this way favor external rupture of an abscess, as the author has personally observed. It may, however, happen, even in cases where the percussion-note is dull over a tumor, that the needle passes through compressed intestines lying between the abdominal wall and the tumor mass. But this does no great harm, as is shown by the cases of puncture performed for therapeutic reasons in meteorism. The author would not, however, have it understood that he recommends exploratory puncture in appendicitis as a necessary and desirable routine measure for determining suppuration. On the contrary, he considers that the procedure is unnecessary for one of experience. He believes that the method has a didactic value chiefly for those physicians who are not familiar with the nature of appendicitis, and who do not believe that all cases of appendicitis are of inflammatory nature. It may also serve to show that quite extensive abscesses may be present in very innocent-appearing cases. Besides this, exploratory puncture may be of a certain amount of value in demonstrating suppuration to people who otherwise refuse operation. The negative result, of course, proves nothing. [It is difficult to understand the author's objections to a rapid exploratory laparotomy for such a purpose.—Ed.]

LUMBAR PUNCTURE

Lumbar puncture attained diagnostic importance for the first time in the hands of Quinke. This writer showed that it is very easy to enter the spinal canal and the subdural space by means of an aspirating needle introduced between the vertebral arches. Fig. 367 represents the arrangement of the lumbar vertebræ in an adult; Fig. 366, that in a child twelve years of age, and shows that the interval indicated by the shaded area is quite sufficient for this procedure. The spinal cord reaches only to the second lumbar vertebra,¹ so that it escapes injury. (See Figs. 366 and 367.) There is also little danger of injuring the cauda equina, because the fibers are sufficiently movable to escape the cannula, and injury to a few fibers would not be productive of any serious trouble. The technic is as follows: The patient is placed on his side and the body bent forward as much as possible, so as to increase the distance between the arches. It is not well to try lumbar puncture with the patient sitting up—at least when performed for therapeutic reasons—as certain disadvantages have been observed due to the change of pressure. Quinke recommended that the puncture be performed between the second and third or third and fourth lumbar vertebræ.

¹ According to Quinke, the cord reaches to the third lumbar vertebra in children under one year.

Subsequent experience has shown that the space between the fifth lumbar vertebra and the sacrum serves just as well and may even be preferable, as the morphologic constituents of the cerebrospinal fluid, such as pus-cells, blood, tubercle bacilli, and trypanosomes, tend to gravitate toward the lowest portion of the dural sac, and might escape observation should the puncture be performed higher. This was shown in a case punctured between the second and third vertebræ, in which the fluid ran clear at first, becoming cloudy later. For the purpose of avoiding error, it is well to count the vertebræ not only from the seventh cervical spine down, but from the sacrum up. It should be remembered that the spines of the lumbar vertebræ are wider and more distinctly separated from each other than those of the dorsal vertebræ; the spine of the twelfth dorsal vertebra, however, resembles the lumbar vertebræ very closely in this respect. It should also be noted that the twelfth dorsal vertebra is marked by the twelfth rib, which starts on the level with its upper border, while the fourth lumbar vertebra lies on the level with the highest point of the crest of the ilium. The needle, to which an aspirating syringe is attached, is introduced under the usual aseptic precautions (see p. 912) in the space chosen, and, according to Quincke, a few millimeters from the median line, so as to avoid the dense ligamentum interspinosum. The point of the needle, however, is directed toward the median line. According to Quincke, the distance to the dural sac in a child two years of age is about 2 cm., and in an adult, 4 to 6 cm. It is just as well

Fig. 366.—Lumbar vertebræ of twelve-year-old child (Quincke).

Fig. 367.—Lumbar vertebræ of an adult with sharply inclined spinous processes closing in the intervertebral spaces.

to introduce the needle in the median line, and it would appear to the author that this procedure is somewhat easier. It should be remembered that in a child the spinal processes are short and are directed horizontally, whereas in an adult they are longer and are directed somewhat downward (Figs. 366 and 367). It therefore follows that in children the needle may be introduced midway between the spinous processes, whereas in adults it is best to keep close to the lower margin of the upper process. If the puncture be made in the middle line then, the needle should be introduced in the middle between two spines. In the case of children the needle should be directed straight forward; in adults it is best to push it somewhat upward, corresponding to the anatomic relations of the vertebral spines.

Lumbar puncture is of diagnostic importance in two ways: It enables one, first, to determine the pressure of the cerebrospinal fluid; and, secondly, to determine its peculiarities. It is self-evident that the pressure of the cerebrospinal fluid is immediately influenced by removal of a portion of it, so that tests to determine pressure should be performed before drawing off any of the fluid. An approximate idea of the pressure may be obtained by allowing the fluid to squirt out through the needle after removing the aspirating syringe. If the pressure be low, the fluid appears drop by drop; if higher, the drops come faster; and if extreme, the fluid may escape in a stream. If the pressure, however, is to be measured accurately, the above experiment should not be performed. The simplest way to measure the pressure is to detach the syringe from the needle and to attach to it instead a

very narrow rubber tube (not wider than 1 or 2 mm.), about 30 to 50 cm. long. This change is done quickly, so as to avoid any loss of the fluid. The open end of the tube is now raised, care being taken that it is not kinked at any place, until the flow of the cerebrospinal fluid just stops; the vertical distance between the tip of the needle in the spinal canal and the mouth of the tube at this point gives a direct measure of the pressure in centimeters or millimeters of water. As any careless manipulation by the operator or vigorous breathing of the patient may lead to aspiration of the fluid back from the tube into the spinal canal, care should be taken to have the tube as well as the needle boiled before being used in this connection. To facilitate this method of measuring pressure the author has devised a metal connection the rounded end of which is slipped within the tube, while the other cone-shaped end is inserted into the butt of the needle. This metal piece is attached to the rubber tube before the puncture is made, so that only a few seconds are spent in attaching it to the needle; almost no fluid is lost, this being important not only to insure correct measurement of the pressure under which the fluid escapes, but likewise to diminish the danger of spreading the infection if the case prove to be one of epidemic meningitis. The use of a specially constructed manometer is obviated by this simple method, which is recommended by Quincke as well. If the tube prove to be too short in any given case, it can easily be lengthened by attaching a second tube, which, of course, should also have been boiled and kept ready for any such emergency. The two tubes are joined in the same manner as the first tube and the cannula; the first tube is provided for this purpose with a metal attachment into which a conical metal piece connected with the second tube may be introduced.

As regards the dural pressure under physiologic and pathologic conditions, it may be said that, in the dorsal position, it is 60 to 100 or 150 mm. of water (5 to 7.3 or 11 mm. Hg) under normal conditions, and 200 to 800 mm. of water (15 to 60 mm. Hg) in pathologic conditions, such as meningitis and tumor of the brain. Increase in pressure is likewise characteristic for the long-continued uremic conditions depending probably upon cerebral edema; estimating pressure in these cases is, therefore, of importance from the diagnostic as well as from the therapeutic standpoint. In the interpretation of figures obtained in measuring the pressure of the spinal fluid it must be remembered that increased pressure probably always means a similar state of affairs in the brain, while normal pressure does not necessarily exclude increased pressure in the brain. That the latter statement is correct is well recognized in case of brain tumors, which often lead to the shutting off of the spinal canal from the ventricles by pressing the cerebellum against the edges of the foramen magnum. The author has seen this likewise in cases of epidemic meningitis, the true state of affairs being shown by a cerebral puncture after the spinal canal has been tapped.

After determining the pressure, a specimen of cerebrospinal fluid may be removed for the purpose of examination. It should be remembered that it is not justifiable, in case of simple exploratory puncture, to remove large quantities of the fluid, because of the dangers that supervene when the pressure is reduced below 60 to 80 mm. of water. These dangers have led certain writers to desist entirely from the therapeutic use of lumbar puncture.

The fluid is either withdrawn by aspiration or allowed to trickle out through the tubes of its own accord. This latter procedure has the advantage of withdrawing the fluid gradually, and of allowing one, by holding the tube at a certain level, to prevent the pressure approaching the danger line, *i. e.*, below 80 mm. This may readily be accomplished by holding the open end of the tube 80 mm. above the site of the puncture.

So far as the peculiarities of the fluid are concerned, it will be found that under normal conditions it is colorless, limpid, and of a specific gravity only a little above 1000 (1003). Under such conditions it contains very little albumin (0.2 to 0.5 per cent.), and shows no distinct nucleo-albumin reaction (p. 570). (See p. 941, Nonne-Apelt's test.) An increase of the specific gravity suggests meningitis, although a normal specific gravity may be present in this disease. Lenhartz claims that more than 0.25 per cent. of albumin also suggests meningitis; although the same writer, in exceptional cases of cerebral tumor and apoplexy, has found albumin up to 1.5 to 2.25 per cent. Spontaneous coagulation of the fluid is an important evidence of its inflammatory origin, just as in other puncture fluids. The macroscopic and microscopic appearance of the fluid is of considerable importance. A cloudy fluid indicates inflammation, as does also the presence of numerous white blood-corpuscles on microscopic examination. These are, as a rule, the cause of the cloudiness. On the other hand, the fluid may remain perfectly clear in cases of

inflammation, especially in tuberculosis and even in purulent cerebrospinal meningitis. Marked cloudiness produced by white blood-corpuscles is in favor, generally speaking, of purulent and against tuberculous meningitis. In tuberculous meningitis the cellular elements are, for the most part, lymphocytes, while non-tuberculous and especially meningococcic or pneumococcic inflammation is accompanied by an excess of polynuclear cells. The lymphocyte content of the cerebrospinal fluid has been recently shown to be of some importance in the diagnosis of tabes dorsalis and of progressive paralysis. In these diseases, as well as in other affections of the nervous system, in chronic syphilitic leptomeningitis, and in multiple sclerosis the lymphocytes are usually found to be increased in number, so that the fluid may even appear slightly cloudy. These findings are especially valuable in differentiating initial stages of the above-named affections from neuroses. It should be remembered that, according to Wegelin,¹ the lymphocyte count of the normal cerebrospinal fluid may rise to 50 per cubic millimeter.² The degree of cloudiness may, under certain circumstances, serve to distinguish between brain abscess and cerebral meningitis, or to establish a diagnosis of a combination of the two, a point which may be of value in determining the advisability of operative interference. A clear fluid in these cases is against, and a cloudy fluid in favor of, purulent meningitis. In case of meningeal hemorrhage and pachymeningitis hæmorrhagica the fluid has been found blood-stained, a point which may be of diagnostic importance in connection with spontaneous cerebral hemorrhages and softening, although, of course, an intracerebral hemorrhage perforating the ventricle would be liable to cause a hemorrhagic cerebrospinal fluid. Hemorrhagic exudates are also met with in tuberculous meningitis. In tumors of the cord and meninges, one should observe whether the fluid contains tumor-cells, but many cases examined by the author with this in view furnished negative results. Quite recently, however, Stadelman has reported a case of carcinomatous meningitis in which he has succeeded in finding cancer cells in the cerebrospinal fluid (Berlin. klin. Woch., 1908, No. 51).

It is of great importance for the purpose of diagnosis to examine the cerebrospinal fluid for bacteria and other micro-organisms. It is best to prepare dry smears for this purpose, the fluid being previously centrifuged or allowed to settle. (See below, Tubercle Bacilli.) In epidemic cerebrospinal meningitis Weichselbaum's *Diplococcus intracellularis* will be found. This was formerly confounded with Fränkel's pneumococcus, although there is little resemblance between them,³ the former being more closely related morphologically and culturally to the staphylococci and still more to the gonococci. The resemblance to the gonococci is so complete that the picture of gonococci on p. 693 may serve to illustrate meningococci as well.

Furthermore, the frequent occurrence of polyarticular inflammation of the joints in cerebral meningitis is in favor of a closer relationship between the meningococci and staphylococci, for there can be no doubt that many cases of polyarticular inflammation are due to coccus infection. The biologic relation of meningococci to gonococci has been demonstrated by Pinto.⁴ The meningococcus stands nearest to the *Micrococcus catarrhalis*, probably being simply a virulent form of this organism. These organisms and the gonococcus have in common their frequent intracellular distribution and their Gram-negative staining reaction, the latter property differentiating them from the common staphylococcus. If simple microscopic examination be negative, culture methods may be used, though it must be remembered that the meningococcus grows only if the spinal fluid be planted as soon as obtained. The organism grows best at incubator temperature on plain agar or, still better, on ascitic agar. Other important excitants of meningitis are pneumococcus, which is often responsible for small epidemics of the affection; staphylococci, streptococci, etc., have been found in other cases. In cases of the African sleeping sickness trypanosomes, with or without streptococci, have been found in the cerebrospinal fluid. In tuberculous meningitis it is quite surprising that tubercle bacilli are found in the puncture fluid in 50 to 75 per cent. of the cases. They are found most easily after allowing the fluid to settle for some time until a coagulum appears, from which a dry preparation is made. (See p. 709.) In cases

¹ Wegelin, Ueber acut verlaufende multiple Sklerose, Deut. Zeit. f. Nervenheilk., 1906, vol. xxxi, p. 313.

² In the Lichtheim Clinic the fluid is diluted with an equal volume of 0.5 per cent. acetic acid, and the cells in a drop of the dilution are counted in a counting chamber.

³ H. Jäger, Zeit. f. Hyg., vol. xix, p. 351. This work contains photographs of the *Diplococcus intracellularis*.

⁴ Jour. de physiol. et path. gén., 1904.

where no coagulum forms the fluid must be centrifuged or allowed to settle for some time, so that the bacteria will sink to the lower layers. Tubercle bacilli are especially easily found if the spinal fluid be mixed with equal parts of alcohol before being centrifuged, the reasons for using this method being the same here as those given in the case of the urine. Should the fluid contain nuclealbumin (pp. 939 and 941), it is well to precipitate this with acetic acid, then centrifuge, and hunt for the tubercle bacilli in the isolated precipitate. (See Examination of the Sputum according to Ilkewitsch, p. 714.) The author has frequently seen mixed infections with tubercle bacilli and meningococci, so that it is advisable, from the standpoint of prognosis, to seek for tubercle bacilli after meningococci have been demonstrated. The fact that tubercle bacilli are so frequently found in spinal fluid, while their presence in pleural exudate is but rarely demonstrated, shows that they probably multiply in the former liquid; this assumption, as well as the finding of miliary tubercles in the interior of the subarachnoid space, seems to the author of significance in explaining the origin of isolated primary tuberculosis of the meninges.

For Wassermann-Neisser-Bruck's serum reaction in syphilis see p. 863.

EXAMINATION OF THE CEREBROSPINAL FLUID BY THE NONNE-APELT METHOD

Equal parts of the spinal fluid are mixed with an 80 per cent. solution of ammonium sulphate, saturated while hot, then filtered and cooled. The specimen is allowed to stand three minutes. Normal spinal fluid shows no change. In certain cases, at the end of three minutes, more or less turbidity is apparent (globulin and nuclealbumin). An essential for the reaction is that the fluid contain no blood, the presence of which would simulate a positive reaction. According to Nonne-Apelt's observations, which have been confirmed by others, the action occurs very frequently in luetic affections of the nervous system, as well as in non-luetic affections which exhibit a lymphocytosis in the fluid. In neuroses, on the contrary, there is no reaction. Nonne-Apelt emphasizes the very important therapeutic fact that the reaction is negative in healed syphilitic lesions. He sees in the reaction a subtle differential diagnostic sign for distinguishing between tabes and progressive paralysis, on the one hand, and neuroses, on the other. According to K. Wirth and Schlesinger,¹ the reaction is also positive in cerebral tumors, infectious diseases, multiple sclerosis, and cerebral abscess.

[NOGUCHI'S BUTYRIC ACID TEST FOR SYPHILIS²

This reaction depends upon the fact that the globulin fraction of the blood-serum and cerebrospinal fluid is increased in syphilis. The increase is usually associated with the appearance of a syphilitic antibody, but is recognizable earlier than the latter. The method of detecting this increase in globulin is as follows: 0.1 cc. cerebrospinal fluid free from blood is mixed with 0.5 cc. 10 per cent. butyric acid solution in physiologic salt solution and the mixture heated over a Bunsen flame; 0.1 cc. of a normal solution of NaOH is added quickly, and the whole is then boiled for a few seconds. The presence of an increased content of protein is shown by a granular or flocculent precipitate, which gradually settles at the bottom of a clear supernatant fluid. This appears in a few minutes to two hours after the second heating, depending on the amount of globulin present. It occurs regularly in syphilitic and parasymphilitic affections, as well as in meningitis caused by *Diplococcus intracellularis*, pneumococcus, influenza and tubercle bacilli; diseases which can, as a rule, be readily differentiated from syphilis by other symptoms. Normal cerebrospinal fluid gives a slight opalescence but no precipitate in less than several hours.

A comparison of the results obtained with this test and those of Wassermann's reaction and the cytodagnostic test is of interest. In a group of cases of hereditary syphilis the butyric acid test was positive in 90 per cent.; the Wassermann reaction in 80 per cent. The butyric acid test was positive in all cases of

¹ See *Neurologische Centralbl.*, 1908; also *Zeit. f. Nervenheilk.*, vol. xxxvi, Nos. 1 and 2. (Bericht der Jahresver. der deutschen Nervenärzte, Heidelberg, 1908.) More recent observations have been made by K. Wirth and Schlesinger, *Mitteilungen der Gesellschaft für innere Medizin und Kinderheilkunde in Wien*, 1909, No. 1.

² Noguchi, *Serum Diagnosis of Syphilis*, J. B. Lippincott Co., Philadelphia, 1910.

cerebral and spinal syphilis; the Wassermann in only 50 per cent. In general paresis the butyric acid test was positive in 90 per cent., the cytodiagnostic test in 91 per cent., and the Wassermann in 73 per cent. In *tabes dorsalis* the butyric acid and cytodiagnostic tests were positive in all cases; the Wassermann in 53 per cent. In psychoses, in which syphilis could be excluded or in which no history of syphilis could be obtained, the butyric and cytodiagnostic tests were positive in 2.8 per cent.; the Wassermann (original method) in 13 per cent.—Ed.]

EXPLORATORY PUNCTURES OF THE BRAIN

Exploratory puncture of the brain, through the skull, during life was first recommended by Maas, and the technic was worked out by Schmidt, Payr, Kocher, Sr. and Jr., Neisser, and Pollack. (For details, see the two last-named writers.) Exploratory punctures of the brain serve to estimate the cerebral pressure in meningitis, brain tumor, and hemorrhage, and they may also be used to aspirate, for diagnostic purposes, fluid (cerebrospinal fluid, pus, blood) or solid tissue-particles (tumor tissues). As in lumbar puncture, the diagnostic procedure is often immediately followed by the therapeutic decompression operation.

Cerebral puncture can be performed almost painlessly with novocain, or with the ethyl chlorid spray, without a general anesthetic. A hand-drill, or a drilling machine driven by electricity or with the foot, may be used for the actual boring process. The drill ordinarily used is a chisel-shaped instrument, such as metal workers employ. Neisser and Pollack recommend drills having a diameter of $2\frac{1}{4}$ to $2\frac{3}{4}$ mm. The author employs a hand-drill, with a handle at the side, and an ordinary bit, 2.5 mm. in diameter, instead of the usual chisel-shaped drilling blades. This bit terminates in a blunt cone, and presents in the longitudinal direction four sharp, screw-shaped edges. It is superior to the chisel previously employed by him, for by reversing, it can be very easily removed from the hole, whereas the ordinary drills are apt to bind. After the example of Middeldorpf and others, the author has had a movable sheath added to the drill, which can be pushed over the blade, and, by means of a screw, so fixed as to regulate the depth of penetration, and at the same time prevent the sudden violent impact of the drill against the dura and the brain, when the resistance ceases after the skull has been perforated. Since the point of the drill is very blunt, the soft parts must first be incised with a sharp, slender knife (cataract knife). This precaution possesses another advantage in preventing the introduction of micro-organisms from the skin by means of the drill.

The technic is as follows: A considerable area of skin around the point chosen for the puncture is shaved, and the point selected is marked with carbolfuchsin. The shaved region is then disinfected in the usual way. The ethyl chlorid spray is used for local anesthesia, and, if desirable, novocain, with an addition of adrenalin (2 per cent. novocain with 0.01 per cent. adrenalin), is injected through the frozen part. An incision having been made down to the bone, the sterile drill is applied perpendicularly to the surface of the bone, and the bone is perforated under light pressure upon the rotating drill. The instant of perforation of the external and internal tables can be easily appreciated. The sheath prevents the drill from entering too far after the bone has been pierced. With a little care injury to the dura can be avoided. The rotation is then reversed and the drill drawn out. It is important to avoid any displacement of the skin, in drilling as well as in removing the drill, so that the perforation may be readily located afterward with an exploratory cannula. After the drill is removed, the skin is cleansed of the accumulated material. In case of hemorrhage it is better to let the blood escape externally than to staunch the flow by closing the orifice, for this might give rise to hematoma. The exploratory puncture is then performed through the orifices, with the syringe described on p. 911. It is advisable to aspirate at first only in the area of the orifice, without going deeper, in order to remove any extradural fluid that may be present. Later on, the dura is perforated by means of the cannula, which is then introduced into the brain, first perpendicularly, then in various oblique directions. Any lateral movement of the cannula must, of course, be avoided, in order to protect the brain. Before puncturing in a new direction, the point of the needle must be withdrawn each time as far as the dura. In order to avoid the blocking of the cannula with brain-substance, Neisser and Pollack recommend that it be armed with a mandrin of fine steel wire, which is removed just before aspirating. As in any other exploratory puncture, it is, of course, necessary to aspirate at different depths. After withdrawing the cannula, the wound is closed with a small piece of

Court-plaster, moistened in bichlorid solution; it heals normally by first intention, but Neisser and Pollack point out that the bone wound, which is closed at first only by granulation tissue, remains permeable to the puncture needle for a long time (three months in one instance), a point that may acquire importance should the puncture have to be repeated later on.

Puncture of the lateral ventricles, at the present time the most important procedure for the clinician, was apparently replaceable by Quincke's method of lumbar puncture for all diagnostic and therapeutic purposes, until it was found that in certain cases, especially in tumors of the posterior cranial fossa, the communication between the cerebral and spinal fluids is interfered with, so that reliable conclusions as to the condition of the brain cannot always be based upon the state of the pressure, or the composition of the fluid obtained by lumbar puncture. Moreover, the therapeutic decompression of the brain is not in all cases so readily accomplished by way of the spinal canal as through puncture of the ventricles. The author recently observed a case of epidemic cerebrospinal meningitis, and also one of brain tumor, in which lumbar puncture had not shown an increase of pressure during the life-time of the patient, although the existence of intracranial pressure was demonstrated at the autopsy.

Reliable topographic landmarks are indispensable for the performance of puncture of the ventricles, in order to reach them with absolute certainty, without unduly damaging the surrounding parts. Of course, only the lateral ventricles are adapted to puncture, puncture of the anterior horns being the most advisable, because probably the least damage is incurred by the necessary injury of the frontal lobes. Kocher selects for ventricular puncture a point in front of the precentral sulcus, between the middle and upper frontal convolutions; this spot corresponds to a point on the surface of the skull, 2.5 to 3 cm. to the side of the so-called bregma, i. e., the junction between the sagittal and coronary sutures. The motor centers are thus avoided, the normal anterior horn of the lateral ventricle being reached at a depth of 5 to 6 cm. The needle is introduced in the direction of the longitudinal axis of the body.

As it is often impossible to feel the bregma, Neisser and Pollack advise that a line be drawn from a point immediately below the nose to the external end of the bony auditory meatus, and a perpendicular be erected on this line, starting at the auditory meatus; this perpendicular should intersect the median sagittal line of the skull at the bregma. Cerebral puncture is fairly free from danger, according to the reported observations, in those cases at least in which it is performed at this typical site. Arterial hemorrhage or profuse venous bleeding may be avoided if the above site for puncture be chosen.

In the exploratory ventricular punctures the same methods of examination are used as in lumbar puncture. The estimation of the cerebral pressure is naturally of the greatest interest, but, unfortunately, very little is known concerning the normal pressure of the cerebral fluid, this weighty question being left undiscussed even in the comprehensive article of Neisser and Pollack. According to Naunyn and Falkenheim, the ventricular pressure in the dog varies normally between 30 and 140 mm. of water. We do not know to what extent these figures are applicable to man. It is known, however, that in pathologic intracranial pressure in man the pressure of the ventricular fluid may approach that of the blood.

Localization of the Individual Lobes and Regions of the Brain (according to Neisser and Pollack).—This refers to brain punctures not only for the purpose of entering the ventricles and evacuating ventricular fluid, but also for exploring the brain substance itself, or the subdural space, at various points. (See Fig. 368.)

Frontal Lobe.—The two points utilized for puncture by Neisser and Pollack are situated in a line drawn backward through the middle of the supra-orbital ridge, parallel to the median line. The first of these points (F_1 , lower frontal point) lies on this line at a distance of 4 cm. from the superciliary margin; the second point (F_2 , upper frontal portion) lies at the same distance higher up.

Cerebellum.—The cerebellum is generally punctured by Neisser and Pollack in the middle of the line connecting the external occipital protuberance and the tip of the mastoid process (point K). The needle strikes the center of the corresponding cerebellar hemisphere (at the lower aspect of the lobus gracilis, emerging above approximately in the middle of the lobulus quadrangularis). In drilling the hole, the instrument must be held perpendicularly to the outer table, according to Neisser and Pollack, and the handle of the instrument must be depressed considerably toward the neck, because the bone surface is by no means parallel to the direction of the skin surface.

Central Convolutions.—In the first place, it is necessary to determine the position of the precentral sulcus (Kocher). For this purpose the sagittal meridian is drawn from the external occipital protuberance to the glabella, and the equatorial or base line as the shortest line between the external occipital protuberance and the root of the nose. The sagittal meridian is then bisected, and a very short line is drawn downward and forward from its midpoint, forming an angle of 60 degrees with the sagittal meridian. This is the so-called *anterior oblique meridian*. Kocher showed that this corresponds to the precentral sulcus almost in its entire length, only the uppermost portion overlying into the central convolution. (See Fig. 368.) When this anterior oblique meridian is divided into three equal parts, the beginning

of the sulcus frontalis superior corresponds, according to Kocher, to its upper third, and the beginning of the sulcus frontalis inferior to its lower third. The course of the middle meningeal artery corresponds to the course of the precentral sulcus, the main anterior branch to the parietosphenoidal sinus. To avoid hemorrhage, therefore, puncture is advisable only in that portion of the central convolution area lying above the lower third of the anterior oblique meridian; Neisser and Pollack recommend keeping from $\frac{1}{2}$ to 1 cm. behind the course of the middle meningeal artery, mapped out as above. The leg-center (C_1) is then reached above the upper third of the oblique meridian, the arm-center (C_2), between the upper and lower third, and the facial center (C_3), at the lower third.

Temporal Lobe.—The following points are suggested by Neisser and Pollack: The first (T_1) lies 1 to 1.5 cm. directly above the upper insertion of the concha (on a line perpendicular to an imaginary horizontal line passing through the infra-orbital ridge and the highest point of the external auditory meatus). The second point (T_2) lies 1.5 cm. further toward the front, in a direction parallel to the imaginary horizontal line.

Parietal and Occipital Lobes.—The posterior oblique meridian is drawn (see Fig. 368) from the middle of the sagittal meridian backward and downward at an angle of 60 degrees; then the nasolambdoidal line is drawn from the apex of the lambdoid suture, which is usually plainly palpable, to the root of the nose. The posterior oblique meridian thus bounds the supramarginal gyrus anteriorly, and the angular gyrus posteriorly, above the nasolambdoidal line, whereas below this line it separates the temporal lobe from the occipital lobe. The boundary line between the occipital and parietal lobes is not clearly defined, and the reader is referred to the illustration for further details. According to Neisser and Pollack, the vascular relations permit safe punctures in these regions.

Points of Puncture for Typical Abscesses and Hemorrhages.—Besides these general rules for punctures in the area of definite parts of the brain,—which are selected especially with regard to the normal topography, and in order to avoid large blood-vessels,—certain special points are designated as affording the best prospects for reaching typical sites of brain abscesses and extrameningeal extravasations by means of puncture. In this connection the following should be mentioned:

Abscess of the Temporosphenoidal Lobe.—The puncture is best made 0.5 to 0.75 cm. vertically above the insertion of the concha (vertically is here used in the sense of the terminology adopted above), perpendicularly to a line drawn through the highest point of the auditory meatus and the root of the nose (T_2 , Fig. 368).

Cerebellar Abscess.—Small incipient cerebellar abscesses, which are usually situated in the sigmoid fossa, may be reached by puncture half-way between two points, one of which, K_1 (see Fig. 368), lies half-way between the external occipital protuberance and the tip of the mastoid process; the other, K_2 , corresponding to the posterior upper angle of the mastoid process (the highest palpable point of its posterior margin). The point K_2 (Fig. 368), which is ascertained in this way, lies in the flexure formed by the sigmoid sinus, but at a sufficient distance from the sinus itself. The puncture must here be directed as nearly perpendicularly as possible to the outer table, which in this locality does not lie parallel with the surface of the skin. The point K_1 is also a good place for the puncture of large abscesses.

Rhinogenous Brain Abscesses.—The lower frontal point F_1 and the point F_2 (see Fig. 368) are points of election for the puncture of these abscesses.

Localization of Hemorrhages.—Kroenlein's two trephining points (see Corning, *Topog. Anat.*, 1907) are the landmarks used in searching for extradural hemorrhages. They are situated on a horizontal line drawn backward from the supra-orbital ridge; the anterior 3 to 4 cm. behind the malar process of the frontal bone, the posterior at the point of intersection of this line with a vertical line through the posterior margin of the mastoid process. (The horizontal direction is here again supplied by the connecting line of the infra-orbital margin with the highest point of the external auditory meatus.) In view of the fact that Kroenlein's points correspond as closely as possible to the position of the anterior and posterior branch of the middle meningeal artery, it is recommended that the punctures be made a trifle posterior to these points, so as to avoid the accidental injuring of the artery.

HARPOONING

To obtain small pieces of deep-seated tissue for histologic examination harpoon-like instruments have been introduced through a cannula and then projected beyond the protecting sheath, to be subsequently drawn back into the cannula with a portion of the tissue desired. As a rule, harpooning is unnecessary, as it is usually possible to obtain sufficient tissue for an examination by using the ordinary aspirator in the manner explained on p. 913. At any rate, the harpoon will be used only in cases where the aspiration fails or where larger particles are desired for the purpose of making microscopic sections. These harpoons may be obtained from an instrument-maker, or they may be improvised by cutting a notch in the stilet of an ordinary trocar. Care should be taken not to have the notch in the stilet so deep that there is danger of the bob breaking off. Harpooning is a much more severe procedure than the exploratory puncture, because, for safety, it is essential that the

harpoon be of a certain thickness. Generally speaking, harpooning has been justly given up.

Von Plesch¹ has recently devised a new instrument for obtaining pieces of tissue for examination without causing the crushing injury resulting from harpooning. It is claimed for this instrument that even a bit of bone-marrow can be removed from a living patient. The advisability of so heroic a method of diagnosis is, however, open to doubt.

EXAMINATION OF THE NERVOUS SYSTEM

Although the technical aids to the examination of the nervous system are usually simple and require but brief notice, it is more important in this department of internal medicine than in any other to conduct the examination in accordance with a definite logical plan. The complex functions of the nervous system make such a plan essential in order that no symptoms may be overlooked, and that the symptoms may be so grouped as to suggest the diagnosis. Such systematic procedure takes time; but it is quite simple and, in fact, often easier than in other forms of disease, since the examiner needs less technical skill. The reason why the beginner finds the diagnosis of nervous diseases so difficult is because he is not familiar with those anatomic and physiologic facts which are absolutely essential for the accurate interpretation of clinical cases.

GENERAL PART

I. PSYCHIC EXAMINATION

The clinician now and then observes in his patient mental disturbances which belong exclusively to the domain of psychiatry. For a comprehensive method of examination in such a case it is advisable to consult text-books upon that subject. In this volume we shall describe those psychic disturbances only which occur so frequently in clinical medicine as to be typical. These include the various grades of depression or irritative disorders of consciousness, delirium, and disturbances of intelligence and memory. Language, which lies on the border between physical and psychic function, will be considered in a separate chapter.

DEPRESSED DISTURBANCES OF CONSCIOUSNESS

The term *somnolence* (sleepiness or hebetude) is applied to the mildest grade of a depressive disturbance of consciousness. This merges imperceptibly into lethargy or stupor, and finally into *coma*, or absolute loss of consciousness.

These depressive disturbances of consciousness are observed not only in brain diseases, but also in all sorts of general affections: 1. In any lethal illness, a short time before death. 2. At the height of infectious febrile diseases, though such diseases rarely produce complete loss of consciousness. 3. In uremia, and then they are generally accompanied by convulsions. 4. In diabetic coma. The deep, often hurried breathing, the so-called air-hunger (Kussmaul), with gradual loss of consciousness, which generally becomes complete, is very characteristic.

¹ Deut. med. Woch., 1906, p. 721, No. 18.

(See p. 99.) 5. In cases of poisoning, especially with alcohol, morphin, chloroform, chloral hydrate, coal-gas. 6. In epileptic attacks. 7. In many hysteric attacks. 8. In focal lesions of the brain of sudden onset, hemorrhage, softening (shock, stroke), in traumatic cerebral lesions (laceration, concussion), in the different varieties of meningitis, and in the later stages of brain tumors.

The disturbance of consciousness noted in *hysteria* is distinctive. If complete, it is ordinarily called *lethargy*. It can be differentiated from the comatose conditions observed in severe brain diseases (apoplexy, uremia, etc.) because it simulates normal sleep so perfectly. This peculiarity (*i. e.*, similarity to sleep) of the hysteric lethargy, enables the experienced observer to differentiate it at a glance from the severer form of disturbed consciousness. It is due essentially to an interruption only of cortical function, so that the phenomena accompanying other forms of coma, which depend upon infracortical disturbances, such as stertorous or interrupted breathing, cyanosis, recognized as grave even by the laity, are lacking. The hysteric condition of lethargy differs from normal sleep in that the former arises and persists under conditions which would prevent or interrupt the latter. Quite a series of transitional forms may occur in the hysteric between lethargy (hysteric unconsciousness) and alert consciousness, *e. g.*, *somnambulism*, in which a person, without any subsequent recollection, may perform all kinds of complicated actions, influenced apparently by no ordinary motives, but by constraining ideas. During the somnambulistic condition the memory seems to be cognizant of what has occurred in previous attacks, whereas in the interval everything relating to the somnambulistic condition is effaced from consciousness (dual personality). These transitions between absent and present, or, better, between waking and sleeping consciousness, may be produced artificially in certain persons by hypnotic, *i. e.*, suggestive, influence, and are, therefore, called *hypnotic conditions*. Wundt regards them as limitations of consciousness; in other words, certain anatomic substrata in the brain are sleeping, *i. e.*, inhibited, whereas other areas functionate much more actively, and in consequence of their isolation, oftentimes in peculiar fashion. A motor phenomenon frequently connected with hysteric disturbances of consciousness is the so-called *catalepsy* or *cataleptic muscular rigidity* described upon p. 961. Such hysteric (hypnotic) conditions associated with cataleptic rigidity are ordinarily designated as *catalepsy*, although the latter expression should really be limited to the condition of the motor system, and not include that of the consciousness.

IRRITATIVE DISTURBANCES OF CONSCIOUSNESS

Delirium is practically the only one of these irritative disturbances which concerns the clinician. It means a dream-like, cloudy state of consciousness, generally associated with hallucinations in which the intellectual capacity is altered in a morbid, irritative way. It does not preclude a depressive condition in other fields of consciousness, and so delirious patients may at the same time exhibit stupor. Delirium is frequently accompanied by *hallucinations* and *illusions*. We distinguish a *noisy* from a *quiet delirium*. The highest grade of the former is the so-called *maniacal delirium*. In *muttering delirium* the patient lies quietly in bed and mutters softly to himself. Delirium may be observed in any severe general condition; it is especially frequent in fever, and then it nearly always denotes a severe sickness. But we should remember that children become delirious more readily than adults, just as in fever their temperatures run higher; and that the weak-minded become delirious very easily. Many acute brain diseases manifest active delirium.

The irritative disturbances of consciousness which accompany the depression in *hysteria* and which occur especially in the so-called "*hysteria major*" as a variety of delirium, should be attributed partly to the lack of inhibition, as a result of depressive states of other fields of consciousness.

The *delirium of alcoholism* (*delirium tremens*) is very characteristic. It is, for the most part, a very noisy, maniacal form, and is almost always associated with hallucinations. The patient sees black forms, mice, bugs, snakes, wires running through the air, a policeman, etc. These appearances have been attributed to the presence of scotomata in the visual field; but if this explanation were correct, the condition would be one of illusions, or of errors in sight, not of real hallucinations. The typical tremor which almost always accompanies *delirium tremens* may decide the diagnosis.

Most cases of quiet delirium which are noticed in patients seriously ill, and which are accompanied by *carphologia* or *floccillation*, render the prognosis rather grave. The patient lies completely oblivious of his environment, continually picking at the bed-clothes, or making motions with his fingers as if he would pick off flakes or scales. *Carphologia*, a symptom which generally precedes death only by a short time, probably depends upon hallucinations.

DISTURBANCES OF THE INTELLIGENCE

These may be independent of any of the disturbances of consciousness, although they are frequently associated with them. The patient's history or a previous acquaintance with him is all there is to aid the

Fig. 369.—Cretinismus (Dr. F. C. Shattuck, Massachusetts General Hospital).

Fig. 370 —Cretinismus. Same case as Fig. 369 after treatment (Dr. F. C. Shattuck, Massachusetts General Hospital).

physician in appreciating the milder grade of disturbances of the intelligence. On the contrary, the severer grade (*stupidity*) and the highest grade (*imbecility*) are evident enough from the facial expression and deportment of the patient.

Any of the incurable maladies may be accompanied by the milder disturbances of the intelligence, *e. g.*, *heart disease*, *nephritis*. Severe disturbances, *i. e.*, marked *stupidity* or *imbecility*, on the contrary, point with much probability to disease of the brain, and, if we except actual psychoses, they point to *brain tumor*, *paralytic dementia*, *multiple sclerosis*, or the after-effects of acute focal lesions of the brain, such as *hemorrhage and softening*. In other cases *imbecility* is the expression of a congenital or early acquired cerebral anomaly (*idiocy* or *cretinism*). The disturbance of intelligence which is observed in *myxedema*, spontaneous or operative (such as after removal of a goiter), deserves special mention. This condition is either very closely related to or identical with cretinism. Such patients exhibit sometimes mild mental disturbance, such as slowness of thought; sometimes, however, a much more serious trouble, bordering on real imbecility.

DISTURBANCES OF MEMORY

Memory is frequently appreciably impaired in old but otherwise quite healthy persons. In other cases it may be affected under the same conditions as the intelligence. In fact, after acute lesions of the brain (hemorrhage and softening) a weakness or even sometimes a complete loss of the memory is very often noticed, and frequently it persists, although the intelligence is not necessarily affected. The so-called traumatic neuroses are very often accompanied by a failing memory.

II. EXAMINATION OF MOTILITY

1. PARALYSIS

To demonstrate paralysis the examiner requests the patient to perform voluntary motions, either without or against resistance. If paralysis of the muscles exists, such a movement is either not performed at all (complete paralysis) or more slowly and less completely than normally (*incomplete paralysis*, *paresis*, *motor weakness*). We easily recognize severe paralysis or even motor weakness in this way. In many instances the posture of the body at rest is in itself so distinctive that we need no attempt at motion to appreciate the complete loss of power. For example, a paralysis of the eye muscles is often evident from the abnormal position of the eyeball; facial paralysis, from the asymmetry of the face; paralysis of the arm, from the dropping and dangling of the arm; peroneal paralysis, from the drooping of the tip of the foot (equinovarus); a musculospiral paralysis, from the *wrist-drop*; an ulnar paralysis, from the characteristic *claw-like* position of the fingers (extension of the proximal phalanges and flexion of the terminal phalanges); a median-nerve paralysis, from the abduction and extension of the thumb, simulating the ape hand. We must, however, always combine inspection with an attempt to secure voluntary movements, since to make a diagnosis it is necessary not only to determine a paralysis, but also to localize it exactly, and so we must test separately the functions of the individual muscles and muscle groups. The cranial nerve-supply will be found upon pp. 1039 to 1094; the nerve-supply of the muscles of the remainder of the body upon pp. 1132 to 1136. If the paralysis be unilateral and not very marked, the examination is made easier by comparing the healthy with the affected side. In this way we can demonstrate a mild

Fig. 371.—Right hemiplegia, organic; excessive flexion of the right forearm upon the arm.

Fig. 372.—Left hemiplegia, organic; sign of the platysma. The paralysis of the platysma upon the left side is evident.

hemiplegia, or, if it be severe, weakness of the trapezius, the respiratory, or abdominal muscles, which otherwise might easily have escaped the

examiner's notice. The rapidity, the force, and the excursion of the movement should all be noted. An excellent method for detecting a very slight one-sided paresis of an arm or a leg is to have the patient raise both extremities as quickly as possible at the same time. The paretic arm or leg will then be plainly seen to lag behind the healthy member, and to fall more quickly from the raised position, even in cases where, in testing the power by movements against resistance, we can scarcely appreciate any abnormality. We can utilize the hand dynamometer to test the strength of the hand.

A mechanical limitation of movement in a joint, or pain incident to its movement, sometimes makes the movement weak, ineffectual, or almost lacking, and so is responsible for an erroneous diagnosis of motor paralysis or paresis. Therefore, before assuming the presence of a motor weakness, we should particularly examine for such a condition of affairs. Of course, patients will have to be believed in regard to the influence of pain upon motility, although they are often very unsatisfactory in their statements. They will acknowledge that they feel pain, but deny that it is responsible for the interference of motion. Frequently they are firmly convinced of the existence of a paralysis until the pain subsides under treatment and permits perfect motion. A sufficiently large dose of morphin administered hypodermically will settle the matter and show that the movement is unconsciously limited by the pain. Such motor weakness is responsible for certain hysteric paralyses where the inhibition of motion outlasts the sensation of pain.

[Babinski has called attention to several aids in differentiating an organic from a hysteric hemiplegia. Two of these are well illustrated in the accompanying cuts (Figs. 371 and 372), and a third in Fig. 378, p. 960, copied from his article.¹—Ed.]

2. PHENOMENA OF MOTOR IRRITATION

(a) Clonic Convulsions or Contractions; Clonic Spasms

By these we mean involuntary muscular contractions repeated in shocks or series, generally with considerable force and rapidity, and contrasted with voluntary contractions badly coördinated. Thus, in spite of the great expense of power, there often results only very slight movement, because antagonistic muscles are working in opposition. An epileptic attack and the typical uremic and eclamptic spasms are types of the clonic convulsion.

Clonic convulsions are never occasioned by peripheral excitation of motor nerves. An accumulating irritative center whose action may be compared to that of a Leyden jar seems to be essential to set off the shock-like explosions. Clonic contractions are practically always occasioned either by a direct or by a reflex irritation of a motor center, whether it be the nuclei or the psychomotor centers of the cortex.

(b) Tonic Convulsions; Tonic Spasms or Cramps

By tonic convulsions we understand long-continued rigid contractions of muscles which may change suddenly and lead to prolonged change of position or tension of the muscles implicated. Tonic convulsions may, under some circumstances, be associated with or even transformed into the *clonic* variety. Tetanus is the type of a tonic convulsion. Tonic convulsions originate in nearly all cases from irritation of some

¹ Gaz. des Hôp., 1900, No. 52, p. 521.

center, and generally reflexly from a nucleus, as, for instance, in tetanus, strychnin tetanus, tetany, and the rigidity of the neck and back in meningitis. The well-known cramp of the gastrocnemius which is

Fig. 373.—Hysteria: blepharospasm. Contrast these two pictures with the picture of ptosis (Fig. 405) (Neurologic Department, Massachusetts General Hospital).

observed in health and in choleraic conditions, but whose genesis is still obscure, belongs to this group.

(c) Contractures

When a joint becomes more or less permanently fixed from contraction of the muscles around it, so that active or passive movements are difficult or impossible, the condition is called *contracture*. The increased tension of the muscle may depend upon increased tonus, i. e., an active (although reflex) contraction, so-called *active* or *irritative contracture*; or it may depend merely upon a nutritive shortening of the muscle, *passive contracture*.

Active contractures are very closely related in their origin to tonic convulsions, and are to be distinguished from the latter only by their relative permanence. In contrast to *passive contracture*, *active contracture* disappears under ether or chloroform; it ordinarily diminishes during a warm bath. Even without narcosis *active contracture* may be sometimes, though not always, overcome by gentle manipulation. Such contractures offer a somewhat elastic resistance to passive movements; they are practically always associated with increase in the corresponding tendon-reflexes; every brusque attempt to overcome the contracture reflexly increases the tension; the muscles exhibit no signs of atrophy; and the contractures exhibit spontaneously a certain slow change or even a gradual transition to tonic convulsions.

Passive contractures, on the contrary, are decidedly resistant to passive movements. They are not especially influenced by chloroform nor

Fig. 374.—Same patient, showing an attempt to open left eye. Note the associated movements of the muscles supplied by other branches of the facial nerve. (See pp. 960 and 1075.)

by warm baths, and they are ordinarily associated with diminution of the tendon reflexes. If overcome by force, which is possible only by a tearing of tissue, they may disappear for a long time. This is a very rare occurrence with active contractures, except the hysteric. For the differentiation of active and passive contractures, Crocq recommends the application of the Esmarch bandage, which, like anesthesia, has no effect upon passive contractures, but causes the active ones to disappear.

Active contractures may occur whenever the muscle tone is increased. Since the muscle tone is of reflex origin, this comes, on the one hand, from involvement of the reflex inhibitory fibers, situated probably in the pyramidal tracts, and, on the other hand, from increased irritability of the reflex centers; therefore, we generally find active contractures associated with lesions of the pyramidal tracts. They cause the characteristic appearance of spastic paralysis. Active contractures usually fix the upper extremities in a position of flexion and the lower extremities in extension, at least in ambulatory cases.

Fig. 375. —Tetany in an infant eleven months of age (Dr Gannett, Massachusetts General Hospital).

This is probably referable to the physiologic ascendancy of the affected muscles over their antagonists, and to the predominance of flexor paralysis in the lower and extensor paralysis in the upper extremities. To explain the varying relations of the flexor to the extensor muscles in active contractures, Mann¹ assumes that the reflex inhibitory fibers for the flexors run with the psychomotor fibers of the extensors, and the inhibitory fibers for the extensors with the motor fibers for the flexors, or, which the author thinks more probable, are identical with them. This supposition coincides very well with the facts demonstrated by Sherrington and Herring (Physiologic Congress in Cambridge, 1898), by means of a very striking experiment on the ocular muscles, that cortical stimulation of a muscle exerts an inhibitory influence upon its antagonists. Consequently a lesion of the pyramidal tract, causing a preponderance of the paralysis in one muscle group, leads to the preponderance of the contracture in its antagonist. Attention must be called to the fact that the typical graded differences between flexor and extensor contractures may be found even in complete

Fig. 376.—Tetany in an infant eleven months of age (Dr. Gannett, Massachusetts General Hospital).

paralyses of an extremity in which there can be no question of a variable degree of involvement of the pyramids for the agonists and antagonists. As Lazarus very properly emphasizes, the physiologic preponderance of power in any one muscle group is sufficient to explain the increased contracture in that group; the more powerful the development of a muscle group, the greater the effect of the reflex increase of tonus.

The contractures in the lower extremities of bed-ridden patients, so frequently seen in transverse lesions of the cord (multiple sclerosis or lateral sclerosis), differ strikingly from those of ambulatory patients. In the former we find extensor contractures in the peroneal group (talipes equinus) only, whereas the knee- and hip-joints are flexed. Although a satisfactory explanation for this has not been given, the author conjectures that the phenomenon is due to the fact that these patients hardly ever exhibit merely contractures, but that they also evidence tonic convulsions of reflex origin which produce flexion of the legs from time to time. They remain in this state for a long time, because of the existing paralysis. In other words, the active contracture is combined with a passive contracture due to a shortening of the muscles. Passive contractures probably assist in the production of equinovarus by downward pressure of the bed-clothes upon the tip of the foot.

PLATE 11.

Kernig's sign in a case of cerebrospinal meningitis. Note the contraction of hamstring muscle, the rotation of the head, the expression of suffering evidenced by the examiner's effort to extend the lower leg, and the pronounced contraction of the rectus abdominis.

Faulty method of determining Kernig's sign. The thigh should first be flexed upon the abdomen before the examiner attempts to extend the lower leg upon the thigh (see accompanying pictures).

A simple interruption of the reflex inhibitory tracts does not seem sufficient to explain the origin of pronounced active contractures. Muscle tonus and tendon reflexes, which pass along the same reflex paths, are generally increased in mere interference of spinal-cord conduction with a lesion of the reflex inhibitory tracts, especially in moderately paralyzed muscles (see p. 992); but a pronounced contracture appears only when a descending degeneration of the pyramidal tracts is super-added. For some unknown reason only descending degeneration seems able to cause active contractures. Perhaps it may be explained by assuming that the lower end of the inhibitory paths, *i. e.*, the pyramidal tracts, even when separated from the source of the inhibition (the central apparatus), still exerts a certain inhibitory influence upon the muscle tone, an influence which does not entirely disappear until after the tract is degenerated down to its lowest termination in the motor ganglion-cells of the anterior horns. Still another factor must be considered to be responsible for the gradual increase of the contracture after the interruption of the pyramidal tract, although such increase runs a parallel and synchronous course with the progressive degeneration of the tract. This factor is the nutritive shortening of the muscles resulting from the prolonged increase of the muscle tonus. Hence, a passive contracture is added to and intensifies at its very onset the active contracture due to the increased muscle tonus. When active contractures depend upon an anatomic lesion and are not purely functional, as in hysteria, they furnish an important sign for the diagnosis of *descending secondary degeneration of the pyramidal tracts, both in the brain and in the spinal cord* (cerebral hemorrhage, softening, tumors, transverse myelitis, cervical hypertrophic pachymeningitis,¹ syringomyelia, compression of the spinal cord, etc.). The contractures may arise in a similar way from primary systemic degeneration of the pyramidal tracts (*spastic paraplegia, amyotrophic lateral sclerosis, etc.*). The mechanism of hysteric contractures is not yet fully understood, nor is the early (at times almost instantaneous) occurrence of contractures of the paralyzed extremities (*contractura præcox*).

Kernig's sign, an important sign in meningitis, belongs to the class of active contractures. When the patient lies flat in bed, there is no contracture; in the sitting posture the legs can no longer be extended at the knee. In other words, the aforesaid contracture appears during meningitis, when the thigh is moderately flexed (no more than at right angles²) upon the trunk. It can be demonstrated either by the flexion of the knees, which appears when the patient sits upright, or by the resistance to extension at the knee-joint when the patient is seated on the edge of the bed, with the thighs at right angles to the trunk. There is a difference of opinion concerning the diagnostic value of this sign in meningitis; although Kernig has expressed himself strongly in its favor in a recent publication.³ Kernig's sign and opisthotonos in meningitis are really due to increased muscle tonus, although the two phenomena do not run a parallel course. A further explanation is that, in healthy individuals, there is a tendency, during flexion of the thigh,

¹ Contractures in cervical hypertrophic pachymeningitis are usually the result of pressure upon the anterior and posterior roots, and hence they belong rather to the type observed during peripheral neuritis.

² Since with pronounced flexion the phenomenon also appears in health.

³ Zeit. f. klin. Med., 1907, vol. xx, pp. 1, 2.

to flex the leg by means of purposeful associated movements (especially on sitting in bed), on account of the biarticular flexors of the leg, which are stretched when the thigh is flexed (hamstring muscles). Whenever the tonus is increased, an increase of this associated innervation must come into play.

According to Rostowzew, Kernig's sign can be the first sign of a beginning tetanus.

Passive contractures may occur wherever the insertions of a muscle are permanently approximated, so that the muscle is gradually shortened in a nutritive sense. This occurs in *mechanical fixation of joints* by bandages which have been applied for a long time or in surgical affections, and *localized atrophic paralyses*, e. g., *infantile paralyses*. In the latter, non-paralyzed antagonists acquire preponderance because of their tonus, dislocate the affected limb permanently in their own direction, and thereby shorten themselves, in the nutritive sense. There is still another type of passive contracture, which arises from contracting connective tissue, which gradually takes the place of a paralyzed and degenerating muscle, and which overcomes the tonus of the weaker antagonists. Here, of course, the contracture is not in the direction of the preserved, but in that of the affected, muscles.

A result of contractures is the fixation of parts which we see so frequently in certain paralyses. These deformities have been variously named according to

Fig. 377.—Claw-hand of ulnar paralysis.

the anomalous position of the limbs. For example, *equinovarus*, in peroneal paralyses, *claw-hand* in ulnar paralysis (Fig. 377), the *ape hand* in median paralysis, the *preacher's hand* in pachymeningitis cervicalis hypertrophica. Special pathology should be consulted for further details.

(d) Fibrillary Twitching (Better Characterized as "Fascicular")

These are brief clonic contractions, not of an entire muscle belly, but of mere individual groups of muscle-fibers. Outside of the small muscles of the hand and face, these contractions do not produce an actual locomotion of the insertion of the muscle, but merely a peculiar trembling or wave-like rhythmic vibration of the muscular mass. The cause of fibrillary twitching is not yet explained. It appears in paretic and atrophied muscles, particularly when of nuclear or sub-nuclear origin (*in spinal and neuritic muscular atrophy and bulbar paralysis*). It may also occur even without paresis or atrophy, e. g., in

the traumatic neuroses. A certain diagnostic significance is often attributed to this phenomenon, because it is an impossible symptom to simulate; but we must be very guarded in drawing conclusions, because the action of cold upon the naked body of some healthy individuals may cause fascicular contractions.

(e) Tremor (Trembling)

By tremor we mean rapid and rhythmic muscular contractions which are relatively but slightly pronounced. They produce movement of the insertions of the affected muscle or the skeletal parts, thus differing from fascicular contractions. In addition to these pathologic forms of tremor, it must be remembered that, under appropriate conditions, *e. g.*, after severe physical exercise, mental agitation, intense cold, etc., tremor also appears in healthy individuals. Diagnostic importance can be attributed to tremors only after these physiologic conditions have been excluded. There are transition forms between *clonic spasms* and *tremor*, as well as between *fibrillary twitchings* and *tremor*. We distinguish between *intention tremor*, which appears only with purposeful movement, and *tremor* which persists during rest. The intention tremor is typically observed in multiple sclerosis. It was formerly regarded as a paralytic tremor, since it was assumed that the disturbed conduction transformed the voluntary impulse into a succession of rhythmic impulses (from which, as physiology teaches, the voluntary tetanic contraction is constructed), and that the muscle lost the greater portion of the separate stimuli. From his recent experience it would seem to the author that this view can no longer be maintained. He has observed that in cases of multiple sclerosis, where the increased tendon reflexes lead to clonic tendon reflexes (ankle clonus, knee clonus, wrist clonus, etc.), the intention tremor in its rhythm often closely simulates the latter. This would certainly indicate that the tremor of multiple sclerosis is nothing else than a clonic tendon or muscle reflex which is excited and maintained by the tension which the muscle experiences during the intended movement. The tremor of multiple sclerosis is consequently a spastic phenomenon, as is probably true of the majority of tremors. This conception of the intention tremor of multiple sclerosis explains why it may gradually assume the character of those less regular arrhythmic contractions which appear during the course of voluntary movements and make them simulate ataxia. The so-called rest tremor is not dependent on voluntary movement, but occurs also during rest. In fact, it may be present only during rest, and may sometimes be voluntarily controlled. This variety of tremor is one of the characteristics of *paralysis agitans*. It is a spastic phenomenon, the cause of which is located above the arc of the tendon reflexes, and has nothing to do with an increase of these reflexes.

To avoid overlooking tremor of any sort, we should observe patients both at rest and during purposeful movements, as well as in positions of the body which require muscular action, *e. g.*, horizontal projection of the forearm and hands with the fingers spread apart.

The characteristics of the well-known tremors are as follows:

1. The peculiarity of *intention tremor* in multiple sclerosis is that it usually ceases during repose and that it is very slight at the beginning of the movement, then gradually becomes more extensive and rapid, until it

seriously interferes with or prevents the accomplishment of the attempted movement. The excursions are frequently so large and the rhythm of the oscillations so irregular that the tremor resembles ataxia; but the attempted movement always keeps at least to its general direction. The tremor of multiple sclerosis is usually more pronounced in the upper extremities.

2. The tremor in *paralysis agitans* is relatively slow, persists during repose, is usually somewhat lessened by purposeful movements, and is inhibited, often for a considerable time, by a very strong voluntary impulse. The rate of the oscillations is usually 5 or 6 in the second. The tremor is generally noticed first in the hands, in which it is especially distinctive. It often resembles certain fine intention movements, like the rolling of an object between the thumb and forefinger. This fact would seem to indicate that the spasm underlying the tremor arises from a cerebral center in which the impulses have a partly coördinated character. The commonly observed hemilateral type of the tremor in *paralysis agitans*, as well as the frequent hemiplegic manifestations, favor its cerebral origin. There is rarely any tremor of the head in *paralysis agitans*, but to this rule there are exceptions.

3. In *senile tremor* there are 4 to 6 oscillations in the second. In less marked cases it is an intention tremor; in more marked cases it also continues during rest. The head and frequently the lower jaw, as well as the upper extremities, are the seats of this variety of tremor.

4. The tremor of exophthalmic goiter and of other *neuroses* (hysteria) is usually fine and rapid (8 or 9 oscillations to the second). It can generally be recognized most easily in the hands when they are extended horizontally with the fingers apart. Purposeful movements of the hands sometimes increase it.

5. *Toxic tremor* may assume varied forms in alcoholics, morphin habitués, in those poisoned by *mercury* and *lead*, as well as in acute and chronic nicotin-poisoning. Alcoholic tremor is characterized by early involvement of the lips, as well as of the hands. It is most pronounced during purposeful movements, and ordinarily disappears after taking a large quantity of alcohol. The toxic tremors are, as a rule, rapid.

From what has been said, there can be no doubt that tremors are essentially manifestations of spasm, even in the cases often spoken of as paralytic tremors, whenever they are associated with paralytic phenomena of the muscles. No matter how we explain tremor, it must be remembered that it also appears as a physiologic manifestation; *e. g.*, in conditions of intense excitement or fatigue. Its mechanism is physiologically performed, as it were. The author believes that tremor, just as every spasm, is to be explained by a damming up of stimuli which causes an explosive, instead of a constant, discharge of stimuli from the ganglion-cells. This is analogous to the spark discharge of an induction apparatus, in contrast to the spray-like brush discharge following low resistance. To continue the analogy to explosive discharges further, we see that the succession of impulses underlying tremors may be based on the stronger stimulation of the motor ganglion-cells; on the one hand, through the central neuron (*paralysis agitans* and nervous excitability) or through the reflex pathways (multiple sclerosis); on the other, because of the interruption of the current of motor impulses (peripheral palsies, fatigue, etc.). It is the same in all these cases: a disparity between the afferent and efferent nerve stimuli. This exposition is no mere hypothesis. It rests upon the well-known and generally recognized property of ganglion-cells to accumulate impulses and discharge them explosively. This peculiarity, a direct result of physiologic observation, suggests a fundamental characteristic of nerve power, for which we have as yet no further explanation. This brings us closer to an understanding of the different types of physiologic tremor.

(f) Choreic and Athetoid Movements

Choreic movements, or *chorea*, are involuntary, and often very extensive and excessive, muscular contractions, but, unlike clonic convulsions, they are not absolutely without coördination. They can be differentiated from voluntary movements by their bizarre character and their aimlessness. In pronounced chorea the entire body is thrown into constant motion, so that any attempt at purposeful movements is often entirely fruitless. Chorea of the facial muscles is exhibited by grimaces; chorea of the breathing, voice, and speech muscles by the choreic articulation, which may render speech quite incomprehensible. Choreic movements are most pronounced in the *neurosis chorea*, in which they constitute the principal symptom. Symptomatically, choreic movements occur in the form of hemichorea in some cases of hemiplegia, especially with lesions of the posterior part of the internal capsule and the optic thalamus (chorea post- or pre-hemiplegic).

Athetosis may be regarded as a variety of chorea. When the involuntary movements occur slowly and very regularly, the condition is called athetosis. Its significance is not essentially distinct from that of ordinary symptomatic chorea. Posthemiplegic athetosis, involving the muscles of the hand and fingers, is the most frequent form.

The muscle unrest observed in *Friedreich's* or *hereditary ataxia* is diagnostically an important symptom. French authors speak of it not unfittingly as "*instabilité choréiforme*." It also belongs to the symptomatic conception of chorea.

Just as in tremor, the mechanism of pathologic choreic movements is physiologically performed, and has a similar physiologic analogy. It is a well-known fact, which we can readily demonstrate on ourselves, that the organism reacts by involuntary, apparently purposeless, movements possessing absolutely the character of choreic movements, whenever it becomes necessary to maintain bodily relaxation for a long period of time. They are evidently intended (in a teleologic sense) to protect the muscles from any harm that might come through the prolonged complete relaxation. They have a voluntary component (as one may readily see) in the feeling that the movement removes unpleasant sensations in the muscles. This sensation and the resulting impulsive movement have been called *anxietas tibiarum* when they appear in the lower extremities. These physiologic choreic movements are most pronounced among the so-called nervous, highly excitable persons, and, although the voluntary component in them is recognized, they appear to be completely independent of conscious sensations and voluntary innervation. They are especially prominent when the compulsory muscle relaxation and also the surroundings at fault produce a feeling of distaste. Probably every one has experienced this who has been obliged to sit for a long time among unsympathetic, tiresome companions, or who has been compelled to attend a long, uninteresting, fatiguing lecture. We might cite, as a further example, the appearance of these movements during embarrassment or other psychic excitement. Adults gradually learn to repress these motor reactions, but their actual existence under the above-mentioned conditions can be easily demonstrated by the way an unspoiled child twists and wriggles when joked with by a stranger or when caught in a lie. The author would like to add, as a further example of physiologic chorea, the movements of the infant before it can exercise voluntary control. Later on, involuntary and purposeless coördinated movements are replaced by voluntary action, which is ataxic at first. Finally, well coördinated voluntary action takes the place of the latter. The choreic apparatus (if the expression may be permitted) persists despite this, and reappears under the physiologic conditions already mentioned, or under certain pathologic conditions. In view of the repeated localization of the lesion of post-hemiplegic chorea in the thalamus, in view also of the existence of the thalamo-rubro-spinal tract (von Monakow), and the so-called quadrigeminate, anterolateral tract, which, together with the pyramids, conduct voluntary motor impulses from brain to cord, it is not improbable that the play of physiologic and pathologic choreic

movements takes place in these secondary motor pathways, and exercises, in a sense, a protective power over the muscular system. Pathologic chorea is evidently founded on an abnormal release of impulses which are in reality physiologic. Contrary to the present trend of investigation, the author believes that the most essential element for the foundation of the pathogenesis of chorea is to give the nature and point of attack of the pathologic irritation. Since we are not able to give a better explanation of the mechanism of chorea, we must consider it a preformed physiologic one. This conception of chorea, for many years adopted in the Bern clinic, renders improbable the oft-claimed, but never-proved anatomic nature of pathologic chorea, especially the post-rheumatic variety, and does not encourage the search for causal anatomic changes. Even if the determinate relation of the *occasional* embolic foci, said to have been found in the brain after post-rheumatic chorea, were established, it would not increase our knowledge of the pathogenesis of chorea. On the other hand, the assumption of an abnormal excitability for the one class of cases, and for the other, an abnormal excitation in the pathways already referred to, would explain its pathogenesis in a satisfactory manner. Might not the remaining peripheral sensory stimuli, no longer painful, but yet uncomfortable, in polyarthritic chorea be the cause of the choreic restlessness?

(g) Associated Movements

These are, to a certain extent, physiologic. They depend upon the fact that intense motor impulses which escape inhibition are switched off to neighboring or more distant muscle territories. Pathologic associated movements are noticed especially when, through some interruption of conduction, the impulse of the will cannot be transmitted in a physiologic direction. A weakening of the physiologic associated movements in the territory supplied by the facial nerve is sometimes of service in suggesting the existence of a paresis of this nerve quite early in its involvement.

Strümpell has described a special form of associated movement as "tibial phenomenon"; it consists of a contraction of the *tibialis anticus* during adduction of

Fig. 378 —Left hemiplegia, organic (combined flexion of the left thigh and trunk); inability of the left leg to remain in contact with the floor while the patient attempts to sit up or lie down with folded arms. The legs should be slightly separated.

the leg. This phenomenon is observed in spastic paralysis, and is regarded by Strümpell as indicative of an anatomic lesion in the pyramidal tract, although healthy persons may, at times, exhibit this phenomenon. It is to be regarded as having diagnostic value only when it cannot be voluntarily suppressed. According to Mann, this phenomenon may also be reversed, the leg being adducted when the *tibialis anticus* contracts. Other associated movements occurring with lesions in the pyramidal tract are, according to Strümpell, dorsal flexion of the great toe

during extension of the leg; the so-called radial phenomenon, which consists of extension at the wrist during flexion of the fingers; and a pronation of the hand which follows the elevation of the forearm from a dependent position, the palm having been directed anteriorly. As a symptom of a lesion in the pyramidal tract, Babinski describes an associated movement occurring particularly in hemiplegia, which consists of the elevation of the paralyzed thigh when the reclining patient sits up or simply attempts to assume a sitting posture. The latter appears to be related to Kernig's sign. (See p. 955.)

In reference to the associated movements of the eyeball in facial paralysis, which have been described as Bell's phenomenon, the reader is referred to p. 1075 et seq.

(h) Forced Movements

These movements, which are sufficiently characterized by their name, are highly coördinated, and so constituted that they can be simulated.

They are especially typified by most of the hysteric spasms, laughing and crying spasms, "arc de cercle," "grands mouvements," and "attitudes passionnées," as well as by many phenomena of convulsive tic. The forced movements, lateral positions, rolling and manège movements of patients with lesions of the median cerebellar peduncle belong to the same category.

A peculiar form of forced movement is the so-called forced laughing which occurs as one of the characteristic symptoms of multiple sclerosis. The laughter of these patients, whether it be spontaneous or the result of external stimuli, is spasmodic and uncontrollable; it apparently arises in the ordinary psychic way, and then, according to the statements of the patient, takes on all the characteristics of a pure somatic spasm. The fact that the forced laughing of multiple sclerosis is associated with a spasmodic condition of the musculature and increased muscle and tendon reflexes would naturally lead us to suppose that the slight motor stimulation and tension of the laughing muscles always produced by the suggestion of laughter-exciting objects or ideas, together with the increased reflex activity of the laughing muscles, is sufficient to throw the laughing mechanism into increased and continued spasmodic action.

(i) Catalepsy; Cataleptic Rigidity (*Flexibilitas Cereæ*)

By catalepsy is understood a peculiar state of the motor system not yet explained, in which the limbs seem to be fixed and to present to passive motion a moderate, wax-like resistance, retaining for a longer or shorter period the position given them. Catalepsy can be differentiated from active contractures by the fact that the parts do not resume their former position after they have been forcibly changed. This cataleptic condition of the muscles occurs in the hysteric, in hypnosis (see p. 947), in the psychosis designated *katatonia*, and sometimes in brain tumors leading to stupor [especially those implicating the corpus callosum.—Ed.]. The author has repeatedly observed this phenomenon in epidemic meningitis during the period of regression.

(k) Myotonia

This is a rare condition of the muscles which, as yet, has been observed only in Thomsen's disease (myotonia congenita). In this affection the muscles appear normal during repose, but when voluntary movements are attempted, assume a characteristic tension which hinders the movements. The tension then gradually diminishes, enabling the movements to proceed in an approximately normal way. (See later, Myotonic Reaction, p. 1027.)

3. ATAXIA, DISTURBANCE OF COÖRDINATION AND SO-CALLED CEREBELLAR ATAXIA

To facilitate better comprehension of this section, it is advisable to read first the section upon Examination of Complicated Sensory Functions, p. 977 et seq.

Ataxia means absence or disturbance of the coördination necessary to the accomplishment of purposeful movements. Coördination is the effectual distribution of voluntary impulses to the groups of muscles which must act harmoniously in each intended movement. Ataxic movements are incoördinated or badly coördinated movements.

Ataxia shows itself clinically by movements which are not necessarily curtailed in power, but which accomplish a result different from the one expected. Ataxic movements produce an impression of insecurity; they either overshoot the mark, or, conversely, do not reach it or reach it in a roundabout way, with loss of time. The movements of a child making his first attempt at walking present the best picture of ataxia; he is not yet "master of his muscles." Ataxia is to be demonstrated clinically by observing how a patient performs voluntary movements. If the ataxia be pronounced, it may be evident in the simplest movements, because even these require coördination of various muscle groups. If less marked, it may be noticed only in attempts at more complicated and finer movements. Ataxia of the lower extremities is usually most noticeable in the patient's gait. A pronounced ataxic gait presents a peculiar rolling, swinging, frequently stamping character. Ataxia of the upper extremities may be tested by having the patient attempt to touch an object, *e. g.*, his nose with the index-finger. If he be ataxic, he will either be unable to do so, or he will succeed only after several trials. In a similar way the lower extremities may be tested for ataxia (the so-called *knee-heel test*: an attempt to touch the knee with the heel of the other foot). Ataxia, both of the upper and lower extremities, is usually increased when the patient's eyes are closed and he is thus deprived of the aid furnished by the sense of sight in correcting his movements.

Ataxia appears typically, and by far the most frequently, in *tabes dorsalis*, in *hereditary tabes*, or so-called *Friedreich's disease*, in *lesions of the motor cortex* (cortical ataxia), in *polyneuritis*, especially in *polyneuritis alcoholica*, and also in *multiple sclerosis*.

In each case the ataxia may arise from a different cause. It seems certain that in children coördination is learned essentially by the sensory control of the movements executed. A child congenitally anesthetic and blind would never learn to perform coördinate movements. Sensory control is necessary for the acquisition of coördination, and probably likewise for its preservation, although perhaps unconsciously. We may, therefore, say that the disturbances of sensibility which occur contemporaneously with ataxia have a direct bearing upon the occurrence of the latter (ataxia of sensory origin). In *tabes dorsalis*, which is usually associated with sensory disturbances, the conception is again acquiring prominence that these disturbances are the essential causes of the ataxia. It is self-evident that the sensibility of the skin is of much less importance than that of the deeper parts,—the joints, muscles, and tendon-sheaths,—which aid us so efficiently in determining changes of position of the extremities. (See

Testing the Appreciation of Posture and Passive Movements, p. 978 et seq.) Therefore, it follows that ataxia need not accompany a pronounced cutaneous anesthesia, provided the perception of passive movements is not affected.

In certain examples of ataxia, however, we cannot determine any coarse disturbances of the deep sensibility of the extremities, so that we must search elsewhere for the explanation. Many authors (especially v. Leyden and Goldscheider) assume, and, as the author thinks, correctly, that the disturbances of sensibility, especially in tabes, are frequently overlooked, because sufficiently accurate methods of examination are not employed to disclose the slight degrees which are present. In fact, it is conceivable that very insignificant disturbances of sensibility of joints, tendons, and muscles are quite capable of upsetting that fine control which is regulated by unconscious centripetal impulses and which persists during movement only for an instant, and yet are so slight that they might be entirely overlooked during a rough test. It should be borne in mind that, by means of the mechanism described upon p. 978, the sensation of innervation for the perception of passive movements of the extremities may also be utilized.

Even after excluding these cases with sensory disturbances which are rather minute and difficult to demonstrate, there still remain other cases in which such an explanation does not apply, and for which, therefore, we must work out some other of the explanations which follow deductively from the theory of ataxia.

Coördination, as we have seen, is accomplished to a certain extent after the manner of a reflex, using the word reflex in its broadest sense. We must assume that peripheral stimulation incites the central organs to transmit, throughout the duration of the movement, just the appropriate amount of motor stimulation to each muscular district concerned. Obviously, such a procedure may be damaged either in the sensory limb of the reflex arc, in the psychomotor center, in its immediate neighborhood, where the centripetal stimulation is transferred to the center, or, finally, in the motor limb of the reflex arc. Injury of any one of these components will probably produce ataxia.

In the so-called *cortical* or *central ataxias*, which are observed in focal lesions of the motor convolutions unaccompanied by sensory disturbances, we must assume that the cortical centers have lost their capacity for carrying out normally coördinated representations of movements and impulses. This form of ataxia, therefore, must be referred to a disturbance of the motor impulses or the sense of innervation. (See p. 972.) We cannot, however, exclude the possibility of such ataxias arising from an imperfect transmission of the centripetal sensory impulses to the motor center, for an imperfect transmission is quite possible, even if the sensory appreciation itself seems normal. Whenever an ataxia of cortical origin is also associated with sensory disturbances for the appreciation of passive movements, the latter difficulty alone is quite sufficient to account for the ataxia, just as it is in tabes. In such cases the only distinction from tabes would be that in the cortical variety the sensory path would be affected much nearer to the motor center than to the periphery. As a rule, those cortical ataxias are not very pronounced, at least in so far as they depend upon an extensive lesion of the motor cortex, because if the cortical lesion be very large, the picture of the paralysis overshadows that of the ataxia.

(Consult p. 974 in regard to the character and recognition of the ataxia due to disturbances of the representations of movement.)

A lesion in the motor limb of the "coördination arc" may also produce *ataxia*, as is well shown by the cases of motor polyneuritis without sensory disturbances. It is clear that a coördinated impulse can accomplish its proper action only when the conduction is perfect, even down to the muscles. If certain ramifications of the motor conduction be affected by serious obstructions, the coördinated impulse is naturally curtailed and ataxia must result. Under these conditions an indication of some motor paralysis would, from the nature of things, be present, and many writers are inclined to exclude such an ataxia with paresis from the true ataxias, and to call it a *pseudo-ataxia*. The author does not consider this justifiable. The characteristics of these cases may be exactly the same as of those of other origin, and even the theoretic difference exists only in a different localization of the interruption of conduction within the aforesaid reflex arc. Moreover, we must assume an interruption of conduction also both in ataxias of sensory origin and in the cortical or central ataxias independent of sensory disturbances. Besides, in cases of polyneuritic ataxia, where the motor limb is involved, the paralysis is sometimes very much in the background or can hardly be observed at all. To be sure, such a paralysis could always be detected if we were able to test the motor power of each muscle individually; but this is not possible, because in general we can test muscles only as groups. Hence slight paresis of individual muscles may readily escape our notice, although it suffices to explain the ataxia. Ataxia may even be caused by mere diminution in the tone of certain groups of muscles, from peripheral disturbances of conduction which cause retarded action of these muscles. This clinical picture of a peripheral conduction ataxia really harmonizes completely with the conception of ataxia, and plainly does not deserve the name *pseudo-ataxia*.

We know that the fibers of the pyramids split up in the cord into collaterals, in a manner similar to the sensory fibers of the posterior columns, and that only these collaterals, as terminal arborizations, are in contact with the anterior horn cells. Hence it becomes possible that a partial lesion of the pyramidal tract in the region of these collaterals may cause an imperfect distribution of motor impulses and produce ataxia.

The above explanation postulates coördination as a complicated reflex which is centered in the cortex. In opposition to this conception, Cyon has attempted to localize the coördinating reflex center in the spinal cord. His hypothesis not only fails to explain cortical ataxia, but is also opposed to our idea of the simplicity and elementary nature of the spinal-cord reflexes. Yet it must be acknowledged that, inasmuch as it determines muscle tonus, the spinal cord does play some part in coördination, because a muscular action takes place promptly and securely only when the muscle at the beginning of its contraction possesses a sufficient degree of tension.

Our hypothesis, nevertheless, does not admit of a special coördinating center in the brain distinct from the motor centers of the cortex, and from this a centrifugal, coördinating tract descending through the cord. Many writers, however, have assumed this. The truth is that all our knowledge of the function of the cerebral cortex, especially our

views upon motor aphasia and the results of stimulating the motor cortex in animal experiments, shows that the cortex is the motor organ of highest development, and that it sends out impulses which have been already coördinated. If, however, as is practically certain, the psychomotor or pyramidal tract transmit coördinated impulses as a direct radiation from the cortical motor center, it is quite incomprehensible what there is for special coördinating centers and coördinating tracts to do. The theory that the degeneration of the posterior columns in tabes involves a special centrifugal coördinating tract, and so leads to ataxia, is thus disproved, even if we disregard wholly the fact (which has been proved both anatomically and experimentally) that the posterior columns are nothing but prolongations of the sensory roots. As a matter of fact, this theory, opposed to the attribution of ataxia uniformly to disturbances of sensibility, was advanced only to explain cases of tabes in which ataxia was found presumably without sensory disturbances. But even if we disregard the probability of having overlooked slight disturbances in sensibility of the deeper parts (especially emphasized by v. Leyden), these cases are easily explained by assuming that the ataxia depends either upon involvement of the representations of movement in the motor cortex or upon lesions of the peripheral motor tracts. Pathologic changes have been found both in the cortex (Jendrassik, see p. 974) and in the peripheral nerves of tabetic patients. As has been mentioned, ataxia may also depend upon a disturbance of muscle tonus. This latter, which is ordinarily very striking in tabes, can readily be explained by the lesions of the reflex collaterals and of the posterior columns, even without any sensory disturbance.

So-called "*cerebellar ataxia*" requires special mention, as symptomatically it does not agree with the picture of ataxia described above, nor can it be explained in the same way. It may be described as a characteristic reeling, both in walking and standing, which is observed especially in patients with cerebellar tumors, particularly when the vermis is involved. This staggering gait, resembling that of a drunken person, is quite different from the gait of the true tabetic. It results from the disturbance of equilibrium which occurs in cerebellar diseases, and is attributed to the relation of the cerebellum to the semicircular canals by means of the vestibular nerve, and also to certain centripetal pathways of the cord (direct cerebellar and Gowers' tracts). *Cerebellar*, as contrasted with true, ataxia is associated with vertigo, and for the most part is noticed chiefly while the patient is walking or standing; whereas, while he is lying in bed, the movements of the legs, as well as those of the arms, may appear quite normal.

There is, however, sometimes a distinct uncertainty in the movements of the arms and legs even in bed, which is suggestive of tabes dorsalis. This will be understood if we remember that no extensive movement of the extremities is possible without some more or less vigorous participation of the sense of equilibrium on the part of the cerebellum in order to correct the altered relations of gravity. The changed muscle tonus, which is almost always demonstrable in these cases, may also play a part in this true ataxia of cerebellar disease. This association of change of muscle tonus with cerebellar affections has been explained by the work of Luciani, which shows that the muscle tonus is diminished by extirpation of the cerebellum. It has previously been pointed out (see p. 964) that a diminished muscle tonus may produce ataxic phenomena. We consequently see that the so-called cerebellar ataxia is made up of two components—the disturbance of equilibrium and actual ataxia. The latter, however, has its own pathogenesis, quite distinct from the usual form of ataxia.

The gait is similarly affected when those centripetal stimulations essential to its rôle as the organ of equilibrium are not transmitted normally to the cerebellum, *e. g.*, in *eye-muscle paralysis* and in *affections of the organs of hearing* which lead to vertigo, especially in *affections of the semicircular canals* (Ménière's disease). The same thing is seen in *hereditary ataxia*, in which it is probably due to the loss of the centripetal impulses conveyed to the cerebellum through the direct cerebellar tract and the tract of Gowers.¹ The posterior columns are usually degenerated in Friedreich's ataxia similarly to tabes dorsalis. We, therefore, find, in addition to the manifestation of cerebellar ataxia, certain other ataxic conditions which correspond completely to tabes dorsalis.

III. GENERAL DISCUSSION OF THE METHODS OF TESTING THE SENSIBILITY

The method of testing the higher senses will be described in the part devoted to the special examination of the cranial nerves. Here we mention merely the testing of the common sensibility, especially of the trunk and extremities.

The work of M. Burchardt, referred to upon p. 1039, should be consulted in regard to the simulation of sensory paralysis, and also p. 969, concerning the impossibility of simulating certain results obtained by testing the pressure sense with von Frey's "irritation hairs."

Remarks on the Selection of Methods for Testing Sensibility.—The author purposely refrains from describing the more delicate methods for testing sensibility, such as Weber's tactile rings, Sieveking's esthesiometer, or the especially constructed thermesthesiometers; although an especial accuracy is claimed for them. This is because he believes diagnosis must depend merely upon gross changes easily demonstrated by the simplest methods. Besides, we either lack a normal physiologic standard or it is so variable with the individual that the apparent precision resulting therefrom may of and in itself lead to erroneous diagnostic conclusions. Finally, such methods require extraordinary patience and persistent practice which cannot be obtained by the ordinary practitioners. Von Frey's method of using test hairs (see p. 968) has a far better outlook.

SENSORY PARALYSIS

Complete abolition of the sensibility of a definite part of the body is called *anesthesia*; a mere diminution of sensibility, *hypesthesia*. In all examinations for sensory defect it is important to have the patient shut his eyes, in order to exclude any visual control of the results, intentional or otherwise.

The examination is complicated, because it includes the determination of the relations of very different sensory functions.

¹ The anatomic foundation for the cerebellar manifestation in hereditary ataxia should also be sought for in pathologic changes in the vestibular nerve or its terminations in the semicircular canals. Such an examination, so far as the author knows, has not yet been made.

(a) Examination of Simple Sensory Functions

Method of Testing Tactile and Pressure Sensibility.—Tactile and pressure sensibilities are identical in character. Pressure sensibility is nothing more than a quantitative estimation of the sensation of touch. Conversely, the examination of tactile sensibility furnishes a merely qualitative estimation of the pressure sense. Among other things in favor of this conception is the circumstance that both senses are localized at identical points of the skin—the so-called pressure points. (See below.)

Tactile sensibility is tested by touching the patient's skin lightly with the tip of the finger, or, in finer tests, by means of a dry camel's-hair brush, and ascertaining whether he feels the touch or not; if so, what he feels and where he feels it. Anesthetic spots can then be marked upon the skin with a dermatographic pencil (p. 217), and the result afterward transferred to a diagram of the body. By means of this test we can sometimes determine a *complete loss of tactile sensibility* over a considerable area; in other cases we can gather from the patient's statements that he appreciates the touch, but less plainly than normal, showing only a *slight diminution of tactile sensibility*. The comparative examination of different symmetric parts of the body is here of the greatest importance. (In regard to the significance of so-called tactile *hyperesthesia* or, better, *hyperalgesia* to touch and of the hyperalgesic zones, compare the section *Sensory Irritative Phenomena*, p. 982 et seq.)

Pressure sensibility or perception, i. e., the quantitative appreciation of the sense of touch, can be tested accurately only when the skin has a firm support, e. g., over the tibia, ulna, and radius. The part to be examined must itself be immobilized. Otherwise, to appreciate the pressure, a patient would make use of his muscular power by balancing, i. e., the innervation sense (see p. 972 et seq.), and the results would no longer be correct. Gross disturbances may be recognized accurately by simply touching the patient's skin with the finger-tip, varying the amount of pressure and having him describe what he feels. For more exact quantitative determination small objects of the same bulk, but of different weight, or, still more accurately, the *baresthesiometer* (Eulenberg's, Fig. 379) may be employed. This is a simple instrument in which a pelotte (a) working upon a spring is applied with varying degrees of pressure to the skin, and the grams of pressure employed can be read upon the scale. By means of this instrument we can determine, on the one hand, the minimal amount of pressure which can be appreciated as differing from a mere touch, and, on the other hand, the amount of the pressure difference that can be felt, i. e., how much the indicator moves before the patient can be sure that the pressure has been increased.

Fig. 379.—Eulenberg's baresthesiometer.

Von Frey¹ has found that the value of the pressure appreciation depends essentially upon the size of the area pressed upon and upon the rapidity of the pressure. The second factor can neither be exactly estimated nor regulated by simple clinical methods, hence the results of the above method are merely approximate. In any case they are of value only if the deviations from the normal are quite striking. It is at all events desirable, in order to establish such deviations, that both the patient and a normal control individual be examined exactly in the same way, i. e., with corresponding areas of skin and equal rapidity of pressure.

In regard to the differences of the value of the pressure appreciation, Weber found that, normally, differences of weight of 1 : 30 can be distinguished by the palmar surface of the third phalanx of the index-finger (excluding the balancing movement, i. e., with the finger lying upon the table). This relation remains almost the same, according to Fechner's psychophysical law, if we alter the absolute size of the burden within wide limits. The rapidity of the pressure probably influences these conditions. Although neglected by Weber, it should be taken into account in making comparative tests. His estimates are based upon quick pressure. In consideration of the insufficient data upon the physiologically normal values, it is advisable for clinical purposes to make control tests upon the corresponding cutaneous areas of a healthy individual under absolutely identical conditions (the same pressure surface and, as nearly as possible, the same rapidity of touch). If the affection be unilateral, it is possible to test the pressure sense by a simple, unobjectionable method. Equal weights (of identical surface and material) are placed as slowly as possible upon symmetric parts of the skin, and the patient, with closed eyes, determines whether one of the weights seems heavier than the other. Unsymmetric cutaneous areas vary so decidedly, even physiologically, in the refinement of their pressure sense, that it is not safe to employ the above-mentioned method of comparison except with the greatest care.

So-called Pressure Points; von Frey's Irritation Hairs.—The quantitative estimate of the pressure sense has been placed upon an apparently more secure basis, since we have known (Blix, Goldscheider) that the pressure sense is not scattered diffusely in the skin, but that it depends upon localized organs. The projections of the latter upon the surface of the skin are called "pressure points," and their anatomic substratum, according to von Frey,² consists both of the wreath-like arrangement of nerve-fibers around the hair follicles, and the Meissner corpuscles. The pressure points are distributed in widely differing numbers to the different parts of the skin. The enumeration of the hairs generally determines the number of pressure points, because a pressure point lies in the projection of each hair follicle, and about 95 per cent. of the skin surface is covered with hair. As a matter of fact, there are some pressure points between the hairs and upon hairless places, e. g., they are specially numerous in the palm of the hand and in the sole of the foot. (On the palm of the hand, according to von Frey, there are at least 100 pressure points to each sq. cm.) These isolated pressure points are the only receptors of tactile and pressure perceptions. A slight touch or pressure carefully localized between them either cannot be appreciated at all or can be appreciated only when the skin is so deformed by the pressure that neighboring pressure points are affected. Von Frey claims that the existence of localized pressure points thus renders possible a strictly localized testing of the pressure perception, and his examination seems to furnish much more trustworthy results than surface testing. In testing pressure points, we first determine the location of the points and then estimate their ability to discriminate pressure. Von Frey's irritation hairs accomplish both purposes most efficiently. They are short spears of hair of varying stiffness, glued at right angles into the end of a wooden handle. Human hairs are employed for weak stimulation, and horses' hairs for strong stimulation. Hairs have two advantages for the mechanical irritation of the skin. In the first place, they act upon very small surfaces of the skin, i. e., they are sharply localized, and, in the second place, the intensity of the irritation can be graded. To estimate the hair's irritation value, we first determine the amount of weight in one scale of a delicate chemical balance which the hair can lift by exerting pressure with its end upon the other scale. The power of the hair, a term which von Frey applies to the weight raised by the hair, is a constant factor for each irritation hair, because a pressure sufficient to balance a heavier weight would bend the hair and consequently diminish its power. By means of such irritation hairs the pressure points cannot only be mapped out, but also sharply localized, and quantitatively

¹ Von Frey, Untersuchungen ueber die Sinnesfunctionen der menschlichen Haut, Abhandlungen der mathem.-physischen Classe der königl. sächs. Akademie der Wissenschaften, 1896, vol. xiii, No. 3, Leipzig.

² Ibid.

stimulated. The irritability or pressure susceptibility of a certain pressure point is to be estimated by determining the weakest hair which can be felt at that point. With hairs of different thickness the diameter, as well as the power, influences the variation of the irritation value, and von Frey has found that the irritation value is proportional to the product of the power and the radius. This product he calls *tension value*. It accordingly measures the pressure irritation value of the hair. Von Frey found the mean susceptibility of the pressure points he examined to equal a tension value of 1.44 gram-millimeters.

The power of any hair will also depend upon its length, since a long hair will be bent by less force than a short one, and it is upon this principle that von Frey's esthesiometer has been constructed. The instrument consists essentially of a strong irritation hair (horsehair), which can be pushed out of a sheath to a greater or less distance, and whose length can be read in millimeters from a scale on the sheath. The millimeter scale is gaged empirically by estimating the power of the projecting portion (by means of a delicate chemical balance) for every fifth or tenth division of the scale. The instrument is manufactured by Zimmerman, of Leipzig. The thickness of the hair must also be measured in order to determine accurately the pressure value of the instrument for a definite length of hair. The radius, multiplied by the power, gives the *tension value* of the hair, which, as mentioned above, is identical here with the irritation value. The examination of the pressure sense should be conducted as follows: The positions of the pressure points are first localized with stronger irritation, and then their susceptibility to pressure estimated with weaker irritations. As yet no clinical experience has been tabulated with this method, but it would seem to the author to possess considerable utility, although less for examining anatomic lesions of the nervous system, wherein only the grosser disturbances are of diagnostic value, than for the examination of *neurasthenic* and *hysterical symptoms*, for the investigation of the action of drugs upon the sensory nervous system, and the like.

Von Frey believes that by means of this method we can demonstrate the oscillating character of the pressure sense, i. e., the periodic increase and decrease of the perception, and even its fatigue. The method may, therefore, perhaps obtain a similar significance as to the demonstration of the fatigue of the visual field in *neurasthenia* and *hysteria*. As contrasted with the latter test (visual field), the results obtained by means of the irritation hairs can in no way be simulated, because the patient is unable to orient himself concerning the pressure points that are being stimulated. Von Frey states that the mean irritability of the pressure points over the entire body is about equal. This is interesting and important for the clinical utility of the method. The local variability of the acuteness of the pressure sense seems to depend more upon the number of pressure points. The rapidity of applying the irritation hairs has but little influence, yet it is better to do it as slowly as possible.

Method of Testing the Cutaneous Sensibility to Pain.—By pricking a patient with a pin, we determine whether the prick as well as the touch is felt and properly localized. It is best to mark the anesthetic and hyperanesthetic spots upon the body and transfer them later to a diagram. In this test special attention should be paid to any delay in transmission of the impression, such as is so common in *tabes dorsalis* and *peripheral neuritis*. A good plan is to have the patient call out the word "now" the instant he appreciates the touch, and the word "prick" the instant he appreciates the prick. A distinct interval often elapses between the two. Von Frey's¹ researches attribute this difference to the increase of a physiologic peculiarity of pain perception, which, in so far as it is mechanically discharged, always possesses a distinct latent stage, which does not exist in tactile perception. It is a well-known fact that the pain caused by stubbing the naked toe becomes more severe after the lapse of an instant. The accentuation of the pain sense, the painful after-sensation, and the repetition of a painful impression (successive polyesthesia) dependent upon a slight prick are all related to this delay and occur under similar conditions.

¹ Loc. cit., p. 242.

Simultaneous polyesthesia is a different phenomenon, and probably depends upon an irradiation or a reflex perception. (See p. 983 et seq.) In this variety several pin-pricks are simultaneously perceived at neighboring spots instead of one single pin-prick. The examination with the pin-prick can be made easier by comparing different parts of the body.

Testing the Sense of Pain by Means of Irritation Hairs; Pain Points.—Von Frey¹ has demonstrated that the appreciation of pain, like that of touch, is not diffused over the skin, but is localized at circumscribed points—the so-called *pain points*.² The territory between these points is insensitive to pain. Ordinary experience with pin-prick at first makes this seem paradoxical until we recall that any sharp mechanical irritation of the skin sufficient to excite pain causes a deformity upon every side. To demonstrate the pain points von Frey has employed the irritation hairs described upon p. 968. The pain points are situated very close together, so that very fine hairs are selected, in order to avoid the skin deformity which would otherwise prevent an isolated irritation; they must, however, possess relatively considerable strength (see p. 968), so von Frey sharpened horsehairs by means of a scalpel under a lens. Experience shows that for demonstrating pain points they are superior to needles, because they do not injure the skin. Such pointed irritation hairs, if possessed of sufficient "power," cause pain, which proves that the painful irritation of the skin from needle-pricks does not depend upon the injury as such. If we sharpen the hair, we can employ the esthesiometer (described on p. 967) to test the pain points. Only by employing these irritation hairs can we be positive that a painful impression is produced immediately at a definite spot, without any trace of a preceding sensation of pressure. Von Frey has further found that the *irritation value* of a hair for testing the sense of pain is equal to the product of its power (see p. 967) and the square of its surface of contact, i. e., its point. He calls this varying power of irritation which decides the degree of pain the *pressure value* of the irritation hair, in contrast with the *tension value*, which, according to p. 968, measures the sense of pressure. He has not yet estimated the mean pressure value of the pain points, but it varies between 20 and 150 quadrimillimeter grams. The number of the pain points varies in different parts of the body between 100 and 200 to each square centimeter. With this great profusion of pain points it is easy to understand why we have only recently learned that pain perception is localized in points. The intra-epithelial free nerve terminations of the skin are thought to be the anatomic substrata of the pain points; they are, therefore, located more superficially than the end-organs of the pressure sense.

Von Frey's researches, as we have seen, prove that actual pain-percipient organs exist in the skin. They are interesting theoretically because they show that pain, a phenomenon which otherwise we should have considered purely pathologic, has been to a certain extent anticipated by nature and has been endowed with physiologic organs. Its importance can be easily understood because the perception of pain in the skin protects the organism from impending dangers (transmitted pressure or actual injury), just as does the pressure sense. Whether the deeper organs also possess special pain nerves is not yet known. At all events, according to the statements made above, the very remarkable richness of the cutaneous pain nerves and the great distress that follows cutaneous injuries seem quite natural from a teleologic point of view.

The investigation of Lennander and earlier surgical experience have demonstrated that most of the viscera (intestine, visceral peritoneum, gall-bladder, kidneys, heart, etc.) do not react to pain after injury. It is probable, therefore, that they possess no special nerves for pain. Furthermore, it is clear that the existence of specific pain nerves would not have the same physiologic prophylactic significance it has for the skin. Whenever an internal organ is exposed to an external stimulus, the injury is done and prophylaxis would be too late; whereas the delicate perception of pain possessed by the skin protects from injury. The sharp pain which so often appears in internal organs physiologically non-sensitive (angina pectoris, migraine, gall-stones) is, therefore, most probably pathologic. It is not caused by specific nerves for pain, but rather by means of a special stimulation of sensory nerves, which in these instances reaches consciousness in the form of pain, although it is normally subconscious.

¹ Loc. cit.

² These pain points must correspond to special end-organs for cutaneous pain, and have their counterpart in special pain nerves, as is proved by the dissociated sensory paralysis in tabes, syringomyelia, etc.

Method of Testing the Cutaneous Thermal Sensibility.—

A sufficiently accurate and very convenient method of testing the sense of heat and cold consists in breathing upon the patient's skin with the mouth wide open and again with it nearly closed. In the former case a sense of warmth, in the latter, of cold, will be appreciated, distinctly, and so characterized by healthy individuals. If any abnormality exist, its location can be represented upon a chart of the body. We can estimate the degree of disturbance more accurately by touching the skin alternately with test-tubes filled with cold and warm water, and determining at what temperatures the water can still be discriminated as cold and warm. By this method we can estimate at the same time the so-called indifferent zone of the temperature sense, *i. e.*, the temperature limits within which the tubes produce an impression neither of warmth nor of cold. These results are valuable only when symmetric parts of the body are compared, or when the results are compared with those from a healthy individual over corresponding cutaneous areas. This method is preferable to that of estimating the minimum appreciable difference of temperature, because it furnishes separate conclusions about the behavior of the nerves for warmth and those for cold. Such a discrimination is necessary, because we know that the organs of warmth and cold sensation are anatomically distinct (warmth and cold points), and that warmth and cold perception may be affected independently of each other. Statements about the minimum temperature difference are of little value, because this difference may vary considerably according to the degree of the temperature used. Fechner's psychophysical law (see p. 968) is of no use, because the ordinary thermometer scales are divided only arbitrarily, and not according to the absolute temperatures. Especial instruments for testing the temperature sense may be desirable for physiologic purposes, but they are superfluous for clinical needs, especially if the principles of examination described here be followed.

An examination of the temperature sense is much simplified and entirely accurate if the disturbances be unilateral. Objects identical in size, shape, and substance, and of the same temperature are gently and slowly placed upon symmetric areas of the skin, and the patient, with eyes closed, tells the examiner upon which side the object feels warmer or colder. This method is of less value for differentiating disturbances which are not unilateral, because non-symmetric areas generally do not have the same temperature sensibility even physiologically.

We are indebted to the studies of Blitz and Goldscheider for the demonstration that, like the pressure and pain sense, the temperature sense also depends upon the existence of localized end-organs in the skin, which are specialized for detecting heat and cold separately. The warmth and cold points coincide neither with the pressure points nor with the pain points. Their relations have thus far been of no clinical significance. Should it be necessary in any case to determine the warmth and cold points, Goldscheider's method is the simplest. It consists in touching the skin with the slightly pointed end of a metallic cylinder varyingly heated. The end-organs of the temperature sense, *i. e.*, the anatomic, substrata of the warmth and cold points, are not yet known.

The author has repeatedly observed, during the development of sensory disturbances, *e. g.*, syringomyelia, polyneuritis, interruptions of conduction in the cord, that articles which ordinarily produce a feeling of warmth in healthy individuals are pronounced cold, and, conversely, cold things are pronounced warm. In other cases warm objects are judged extremely warm, or cold extremely cold. This has

led the author to conclude that thermal sensibility operates according to the Young-Helmholtz or Hering theories of the perception and recognition of different colored lights. These two theories have overcome the great difficulty of the latter hypothesis, namely: that the retina ought to possess special end-organs for every tone or wave length, by reducing perception to merely three colors. This agrees with the practical results of the three-color process and permits us to perceive the entire spectrum. Every wave length excites in a varying degree all, or at least two, of the three sets of fibers, and thus, by means of this variability, every wave length or color is given its proper and characteristic value. Likewise we must assume that the nerves for warmth and cold are stimulated together, during perception of temperature; the former obviously more stimulated by high, the latter by low, temperatures. According to the variable quantitative mixture of stimuli to the nerves for warmth and cold, the sensation, by means of a psychologic process, becomes a thermal perception. This hypothesis explains the phenomenon of intensification or reversal of the sensation for warmth and cold under certain conditions instead of a mere thermal hypoesthesia or anesthesia, when the excitability of the nerves in question is either diminished or lost, since the sensation corresponding to the better preserved thermal fibers will thus outweigh that of the paralyzed group, or, conversely, the sensation corresponding to the latter group will be reversed.

Method of Testing the Sensation of Motor Innervation, or the So-called Sense of Strength; Judgment of the Coördination of Volitional Impulse.—By innervation sensibility is meant the ability to estimate the measure of voluntary movement impulses during the movement itself. The coördination of volitional impulses is, to be sure, dependent upon the correct sensibility for the innervation of the individual muscles. One speaks of this capacity as the sense of strength, in so far as by means of muscular power it serves to distinguish differences in weight. The designation *power sense*, or sense of strength, is really incorrect, because neither a separate sense nor special sensory nerves preside over this function. It is much more plausible to assume that the innervation sense differs from the actual sensory function by having its origin in the motor centers and not in the periphery. Probably the conscious coördinated volitional impulse itself is identical with the innervation sense (*i. e.*, the idea of a movement in progress of becoming externalized or reaching the intensity of a volitional impulse). The expression *strength sense* or “power” sense can be justified only by its brevity and intelligibility. In reality the examination of this function might be considered quite as well under motility as under sensibility.

An entirely isolated test of the sense of strength is difficult, strictly speaking impossible, because the pressure sense simultaneously stimulated by the lifted weight is bound to influence the result. For practical purposes, the test is performed in this way: Different weights are hung in a cloth sling looped about the hand, forearm, or foot, lifted by the patient, and then discriminated. At the same time the normal relations are best preserved by practising the same experiment upon control persons with healthy nerves, *e. g.*, upon the examiner. By this method we are able to determine not only the absolute estimation of weight, but also the estimation of differences in weight which, in pathologic cases, are thought to be either too small or too large, *i. e.*, misjudged. The results are of diagnostic value only when they are very striking, because people’s ability to differentiate weights by the innervation sense varies, and is to a great extent influenced by practice.

In this examination two devices may be employed to aid in excluding the pressure sense. One is to make the sling holding the weight very broad, so that it will extend over as large an area of skin as possible, and so reduce the pressure sensation below the value for which Fechner’s psychophysical law holds. A slight increase

then in the weight will not influence the pressure sense. The other device, supposing we wish to estimate the strength sense of the arm, is for the patient to hold the sling with the strongest possible pressure of his hand. Here, conversely, the strong hand pressure has the effect of making the sensation of pressure so strong that, according to Fechner's law, a slight addition of weight will not appreciably increase the sense of pressure, but merely that of muscular fatigue. E. H. Weber has made use of the latter device for testing the strength sense. He found that the strength sense of the arm could appreciate differences of weight of 1 : 40, whereas the pressure sense alone of the fingers appreciated differences of 1 : 30. (See p. 968.) His researches also showed that a combination of the pressure and the strength sense do not furnish much better results than the strength sense alone. The principle of test can also be applied to the lower extremities by fastening the sling which carries the weight to the leg by means of a strongly tied knot.

Besides weights, the strength sense can also be tested by means of Eulenburg's baresthesiometer (see p. 967, Fig. 379), with this difference, however, that the part to be examined, *e. g.*, the terminal phalanx of the finger or toe, must be balanced by muscular action not supported artificially. This method does not furnish us with the estimation of the sense of power exclusively, but rather the sum of the sense of power plus pressure sense.

Even excluding the influence of the pressure sense, the results of these tests do not always furnish direct conclusions upon the "innervation" or "strength sense." The discrimination of weight may be affected by disturbances of innervation sense which are localized in the psychomotor center, and by motor pareses, because in such cases an especially vigorous impulse of the will is required to lift a weight. Whether to credit a disturbance in the discrimination of weight to an actual involvement of the "innervation sense" or to an error in judgment due to motor paresis, must be determined from the results of an examination such as we have described above, and especially from the condition of the motility. Actual affections of the innervation sense must be attributed to functional or anatomic lesions in the region of the motor cortex.

The innervation sense, in so far as it is tested as a sense of strength, always refers to the entire group of muscles which together exercise the necessary coördination for lifting a weight, and any disturbance detected must affect equally the entire group of muscles in question. It is conceivable that the disproportion between the capacity of the muscles and the sense of innervation affects only individual muscles in a group. In such cases the trouble is less a disturbance of the sense of strength than one of coördination, in that one muscle receives too much innervation for the accomplishment of purposeful movement, the others too little. On reflection it will be seen that here we are in reality only considering the two cases of ataxia alluded to on p. 963 et seq., namely, cortical ataxia from disturbances of the cortical coördination impulses, and an ataxia from partial motor paralysis (so-called pseudo-ataxia). In the *cortical form* the ataxia depends upon the actual disturbance of the innervation sense; in *partial motor paralysis*, on the contrary, while the innervation sense, as such, is correct, the impulses transmitted to the muscle are quantitatively incorrect, and, therefore, the resulting ataxia simulates a falsification of the innervation sense. Before attributing the ataxia in any given case to disturbance of the innervation sense or cortical coördination, every other possible cause of ataxia must be excluded, *e. g.*, other disturbances of motility, disturbances of the sensibility of passive movements, and anomalies of the muscular tone. If the examination disclose abnormalities of the muscular sense, the diagnosis will be strengthened. Still, the presence of such anomalies

is not absolutely necessary, because the power sense of every individual muscle cannot be tested. Just this kind of cortical ataxia has sometimes been noted in focal lesions of the motor cortex. But even in *tabes dorsalis*, should an actual ataxia appear without any disturbance of sensibility, cortical ataxia may possibly play a part, because, according to Jendrassik's researches, this disease presents, in common with general paresis, a degeneration of the tangential fibers of the cerebral cortex.

The So-called Sense of Location, Better Described as the Ability to Localize Sensations.—There is no special sense of location, for every sensory representation has its own place, *i. e.*, it is localized or referred to a certain part of the body. Physiologic psychology claims that each sensation produces a so-called local sign in the sphere of consciousness, depending upon the fiber from which it is discharged. These local signs become indistinct if the intensity or distinctness of the impression itself be impaired. However, we scarcely notice any disturbed localization provided the impressions themselves are perfectly intact. On the other hand, indistinct impressions and inexact localizations go hand in hand. The so-called associated or reflex impressions (see p. 982), together with the indistinctness of the local signs, are much more apt to be the cause of inexact localization in diminished sensibility. Such reflex impressions arise quite readily in interruption of sensory conduction from the lateral dislocation of the impulses through the collaterals of the sensory tract.

Slight disturbances of the location of sensation are sometimes observed in parts in which the paralysis is purely motor. They are due to the absence of the daily exercise of localization and of the continued refreshing of localization by movement, and are explained by the fact that the actual conception of space and the sensation of localization are acquired ontogenetically through motility only, and consequently require motility for their intact preservation.

The power of localizing sensation is best investigated by applying the touch, pain, and temperature tests to the area to be investigated, the patient having his eyes closed, and then requiring him to open his eyes and locate with his finger the spot at which he experienced the particular sensation; or, if this be impossible on account of motor disturbances, to describe its location. The difference between the point irritated and the point indicated by the patient, expressed in centimeters, indicates the degree of the error in localization. Absolute values for the normal error in localization cannot be given, since they are subject to great individual variations and are markedly influenced by practice. It is consequently best to compare the investigated area with the opposite healthy one, or, if this be impossible, with the same region in another person of similar physical and mental characteristics. In view of the influence of practice, only marked errors in localization are of diagnostic importance.

The So-called Muscle Sense or Muscular Sensibility.—What we have described above as the innervation sense is often confused, under the common title of *muscle sense*, with the appreciation of active and passive movements, to be described later. Such a special muscle sense does not really exist, and the obscure term leading to a misconception should, therefore, once for all, be dropped.

Method of Testing Bone Sensibility; the So-called Sensation of Vibration.—M. Egger¹ was the first to demonstrate the feasibility of testing the sensibility of the bones by applying a vibrating tuning-fork to them. The examination

¹ Jour. de Physiol. et de Pathol. gén., 1899, vol. i, No. 3.

was suggested by the extreme sensitiveness of periosteal lesions. If we set a C tuning-fork of 132 vibrations or an ordinary A tuning-fork of 440 vibrations upon the surface of a bone, the person examined normally perceives a characteristic thrill or tremor. Egger believes he has demonstrated that this perception in pathologic cases is entirely independent of the absence or presence of cutaneous sensitiveness, and has proved that it is actually peculiar to the osseous system. It may be retained with a diminished cutaneous sensibility or lost when the latter is normal, despite the fact that the vibrations are naturally transmitted to a considerable distance. Egger found that this thrill was strictly localized, so that under pathologic conditions the tuning-fork was appreciated at one spot of a bone and not at a neighboring spot. He also demonstrated a hyperesthesia of the bones, for they could appreciate the vibration of a high tuning-fork (vibrating 2048 times), although this normally is not perceptible. Bone anesthesia occurs especially frequently in the ataxic stage of tabes. The occurrence of disturbances in the appreciation of passive movements is, however, independent of the bone sensibility. In many cases of tabes, and especially in the initial stage, tuning-fork vibrations produce a sensation of burning as well as a thrill (hyperalgesia of the bones). In the trophic changes of the joints and bones in tabes, the disturbances in bone sensibility are usually found in the vicinity of the affected parts. Disturbances in bone sensibility also occur in *syringomyelia*, and mostly in the diffuse areas of anesthesia so characteristic of this disease. In *Brown-Séquard's unilateral paralysis*, the osseous sensibility, like that for passive movements, and in contrast to the cutaneous sensibility, suffers upon the same side as the motor disturbance. In *cerebral hemi-anesthesia* bone anesthesia is localized upon the paralyzed side, although it is ordinarily incomplete upon the head. Bone sensibility varies in *hysteric anesthetics*. Frequently, though not constantly, the bones share in the anesthesia. In hysteric conditions the bone, as well as the cutaneous, sensibility not uncommonly suddenly reappears under the influence of the tuning-fork vibrations. Bone anesthetics sometimes of equal, sometimes of less, extent than the sensory disturbance of the skin, also are found in *transverse lesions of the spinal cord*. In the latter case the bones of the lower end of the leg are ordinarily most affected. From the pathologic findings Egger believes that the tracts for bone sensibility take an uncrossed course in the gray matter.

Egger's supposition that the vibrations of the tuning-fork are perceived only through the bones has recently been shown by Goldscheider¹ to be erroneous. The soft parts are also susceptible to these vibrations, but not to so great a degree, since they are unable to vibrate as synchronously. Goldscheider found, in contrast to Egger, that the perception of tuning-fork vibrations is partly dependent also upon the condition of cutaneous sensibility. One way in which he proved this was by anesthetizing the skin with cocaine. The cutaneous sensibility and the osseous sensibility to tuning-fork vibrations may be separately tested by pressing the tuning-fork softly against the part for the former, and firmly for the latter. In the first instance the vibrations remain upon the surface, while in the second they are conducted to the deeper parts through the compressed skin. Goldscheider calls the perception of the vibrations of the tuning-fork the sensation of vibration, and regards it, not as a specific sensation, but as an expression of the sensation of rhythmic interrupted irritation of the nerves that are responsible for the sensations of contact or pressure. Rydel and Sieffer² call this quality of sensation "*pallesthesia*" (*πάλλω*—I shake). In spite of his objections to the conception of Egger, Goldscheider regards the test with the firmly applied tuning-fork as the best procedure for the estimation of osseous sensibility.

The author agrees with the view that the perception of tuning-fork vibrations is not a special bone sense, but rather the perception of oscillatory irritations through the nerves for touch and pressure sense in general. The specific part lies merely in the rhythmic character of the stimuli, which the bones are especially fitted to perceive in virtue of their capacity for vibrations.

We can prove that we are concerned chiefly with excitation of the nerves of touch and pressure sense, because we can demonstrate on ourselves an oscillatory quality of excitation for these nerves only. (See p. 969.)

Whether or not pain stimuli can have a similar vibratory character remains to be proved. We know, however, that certain forms of pain have the character of a vibration, *e. g.*, after contusion of the ulnar. But this is possibly due to association with the vibratory sensations of touch and pressure. Many observations have led the author to believe that the test of the sense of vibration is really an extremely

¹ Berlin. klin. Woch., 1904, No. 14.

² Arch. f. Psychiatrie, 1903, vol. xxxvii, p. 488.

delicate test of touch and pressure senses, which possesses clinical value by reason of this delicacy. By means of the tuning-fork, he has often demonstrated in tabes dorsalis transverse lesions of the cord and cerebral affections, sensory disturbances which would otherwise have escaped detection.

It has also proved itself of value in segmental localizations, in that, on the one hand, it alone sharply differentiated the limits of the sensory disturbance, or that, on the other hand, it overlapped the limits established by the usual test of contact sensation.

It seems that the earliest disturbance appears as an inability to perceive impulses of short duration as separate vibrations.

From this stand-point the method is to be recommended as part of the clinical armamentarium, although it cannot be denied that in some cases the ordinary test of the contact sensation betrays disturbances which the tuning-fork fails to show. These are, however, obviously exceptions. In order properly to utilize the method, tuning-forks of different vibrations must be employed, and the results of each carefully recorded. Rydel and Seiffer (*loc. cit.*) elaborated a quantitative method for the use of the tuning-fork. They recommended a tuning-fork provided with a Gradenigo triangular block on one arm, whose amplitude of vibration should be read at the instant the vibration ceases to be appreciated. The tuning fork most useful for this test is the C fork (128 vibrations) fitted with a Gradenigo triangle.

THE FARADIC TEST OF SENSIBILITY

Test of the Sense of Faradic Vibrations

The electric testing of sensibility has been intentionally disregarded in the former editions of this work, because the method was not sufficiently perfected, and also because we are really uncertain of what we are testing. This restriction at the present time will be applied merely to the galvanic testing of sensibility, because in this instance direct stimulation is complicated by the electrolytic or chemical stimulation of the cutaneous nerves, which is an additional factor that cannot be reckoned quantitatively. Subsequent examinations have, however, led to the conclusion that testing by means of a faradic current when the interrupter swings free has clinically the same characteristic significance as the tuning-fork vibrations, *i. e.*, it is a more delicate test of contact and pressure sensations. If the current be not strong enough to cause pain, faradic stimulation of the body surface with a freely swinging interrupter produces a sensation of vibration which cannot be differentiated quantitatively from the sensation of a vibrating tuning-fork. Since a vibratory character does not appear in qualities of sensations other than that of touch and pressure in the ordinary every-day life (see p. 975), we may well assume that the sensation of faradic vibrations, if the term may be permitted, has the same significance as that of tuning-fork vibrations, and is due to an oscillatory irritation of the nerves for touch and pressure sense. The author's investigations have taught him that the same rule holds for the faradic vibrations as for the tuning-fork; namely, that early disturbances can be detected more readily than with any other method of testing sensation. It is, however, obviously necessary that the current produce the sensation of vibration only and be weak enough to avoid every painful sensation. As soon as painful sensations appear, it can no longer be considered as an improvement of the examination, and the result will be ambiguous. For this reason we cannot use the well-known sensory electrode of Erb, which consists of a bundle of thin copper wires bound together with a non-conducting substance, the cut ends of which are placed dry on the surface of the skin. This electrode, in consequence of the condensation of current and the uncertain contact, does not readily allow us to exclude pain stimuli. The moist electrodes used ordinarily in testing motion are to be preferred. (See p. 1011.)

Many clinical observations have shown that the electric method of testing sensibility has the same value as the tuning-fork for the demonstration of differences of sensation and their boundaries in one and the same patient. It possesses certain advantages over the latter. It seems simpler from an instrumental standpoint, and one can modify conditions during the experiment by altering the strength of the current or the manner of oscillations of the interrupter, which can only be achieved with the tuning-fork by the use of a number of forks of different tones. There is this disadvantage, however, that the results of different faradic apparatus, as well as tests undertaken at different times, cannot be compared one with the other, both on account of the difference in the amount of electric energy used, and the impossibility to fix a definite standard for the number of oscillations of the ordinary inter-

rupter. Thus the results of the faradic test of the sensation of vibration are positive only in so far as they are comparative at the time they are obtained. To be sure, this degree of objectivity is sufficient to establish disturbances of sensibility and their boundaries.

The question, whether or not certain variations, founded on the difference in the quality of the stimuli, appear with the general agreement between the electric and tuning-fork tests of the sense of vibration, must be deferred until further investigations have been made.

METHOD OF TESTING THE SENSATION OF MUSCULAR CONTRACTION (Curschmann)

H. Curschmann, Jr.,¹ employs the following method for testing the sensation of the contraction of muscles (not to be confused with the sense of innervation). (See p. 972.) The extremity is placed so as to avoid, during the contraction of its muscles, any friction between the cutaneous surface and the support, thus preventing confusion with the cutaneous sensibility, and the amount of current necessary for the minimum cathode contraction of the muscle to be examined (in case of reaction of degeneration, anode contraction) is determined. The patient is told to close the eyes and see whether he can perceive a movement in the given muscle area in addition to the pricking pain of the closure of the current. If intelligent, he can distinguish between the sense of contraction of the muscle and the sense of movement of that part of the extremity. He must then indicate the appearance of the sensation of contraction during gradual increase of the current; always with the precaution that he indicate with his finger the muscle in question. H. Curschmann found that in healthy individuals the sensation of contraction has a standard value several milliampères lower than that necessary for the minimal contraction. It is never higher.

Curschmann found considerable variation from the normal in diseased conditions, *i. e.*, tabes, hemihypesthetic hemiplegia, syringomyelia. In these diseases the disturbances generally increase as we proceed from the proximal to the distal end of the extremity. He considers this behavior very important in the differential diagnosis between hysteric and organic hemianesthesia. They are almost always present in the area of dissociated sensory disturbances of syringomyelia, whereas in multiple sclerosis they may be present where there is disturbance of motility or may be completely absent in spots. Where muscles show reaction of degeneration, the perception of contraction is usually much diminished or disappears.

(b) Examination of Complicated Sensory Functions

Method of Testing the Perception and the Judgment of Active Movements of the Extremities.—Even with closed eyes a healthy person has a very exact knowledge of every change of posture of his extremities, and graduates his motor impulses accordingly. These perceptions of movement depend primarily upon the innervation sense (see p. 972 et seq.), *i. e.*, upon the judgment of the impulses of contraction which the individual muscles receive in a certain position, and, secondarily, upon the sensibility of the deeper portions of the extremities, *i. e.*, of the muscles, joints, tendon-sheaths, and even of the skin. They are, of course, compressed and stretched differently in every change of posture. So this performance does not depend merely upon a particular sensory function, but upon the cerebral reception of several sensory impressions aided by the innervation sense, which belongs in reality to motility. Affections of the appreciation and judgment of active movements are, therefore, encountered as often in sensory disturbances from peripheral interruption of conduction as in lesions of the psychomotor centers or tracts, in consequence of an impaired harmony between the degrees of voluntary impulse and the resultant movement. Yet, when the cause of the affection lies upon the motor side, the sensibility of the deeper parts can, to a certain extent, perform vicariously

¹ H. Curschmann, Deut. med. Woch., 1905, No. 31.

the function of the impaired judgment of the condition of muscular contraction; and, conversely, when the defect lies upon the sensory side, the innervation sense can compensate a certain part of it. It appears that this vicarious performance of one function by another is possible, and varies somewhat with the individual.

To test the appreciation of active movement, we direct the patient either to describe as accurately as possible a position of his extremities, which he voluntarily assumes and alters while his eyes are closed, or to touch with an extremity an object whose position he has noted before he closed his eyes, employing the shortest and most direct movement possible. In the latter experiment any disturbance of the function in question is manifested by the ataxic character of the movement and by its lack of certainty. This test, then, is like that for ataxia. But although absence of ataxia proves that the patient judges his voluntary movements correctly, nevertheless, if ataxia be demonstrated, we require further evidence to decide that it is accompanied by a failure in the appreciation or judgment of active movements. The latter function may be absolutely preserved and the patient may be perfectly cognizant of the ataxic peculiarity of his movements with closed eyes, yet be unable to execute them coördinately if the motor elaboration of his movement impulses be defective. We need the most accurate analysis possible, and a consideration of all the conceivable causes of ataxia, in order to decide if the ataxia proves faulty judgment of the patient's own movements. Should the muscular tone (p. 964) be normal and no sign of motor weakness be present (p. 963), we must attribute the ataxia by exclusion to a disturbed central motor coördination or to imperfect impulses. Then we must decide whether such an affected judgment depends upon an actual disturbance of sensibility or of the innervation sense, *i. e.*, a faulty representation of movement (p. 963). If the former, the appreciation of passive movements will also be affected. As we have already mentioned, this is the commonest cause of ataxia. (See p. 962.) It is also worth noting that an intelligent patient, simply by his own observation, can often decide correctly whether his ataxia is due to a disturbance of sensation or to a faulty sense of motor innervation, *i. e.*, coördination impulse. Actual disturbances of sensibility are the usual causes of the ataxia in tabes dorsalis, but a disturbance in the innervation sense or in the representation of movements may cause ataxia in cortical affections, without any true disturbance of sensibility.

Method of Testing the Appreciation of the Position and of Passive Movements of the Extremities [Postural Perception.—Ed.].—In estimating a passive change in position of the limbs, the innervation sense is of no assistance. We judge of it purely in a sensory way by employing the sensibility of the deeper parts, muscles, fasciæ, joints, etc., and in part through the skin (perception of the differences in tension). Theoretically considered, the appreciation and judgment of active movements must be easier than those of passive movements, because the former utilizes more aids (*e. g.*, sense of innervation). Therefore, even where the appreciation of active movements be intact, that of passive movements must still be tested for. It is done in this way: The patient, with closed eyes, is asked either to describe passive changes of position in his extremities, or to imitate them with another extremity whose innervation has not been involved. This will not be possible if the appreciation of passive movements be affected. Yet

it is to be noted that, under some circumstances, the patient can compensate moderate disturbances by informing himself of the position of his extremities through the appreciation of muscular contractions by means of the innervation sense. (See p. 978.) In this way we may perhaps explain the frequently observed fact that the estimation of passive alterations of posture is comparatively well preserved in moderate sensory disturbances of the extremities, although this gives us no right to assume that the sensibility of the deeper parts has escaped. To obtain clear results in such cases we must demand of the patient a practically complete muscular relaxation. In most cases disturbances in the appreciation of posture show themselves without anything further by an ataxia, because of the failure of the essential sensory control of the movements. Hysteric disturbances of sensibility present an exception to this rule; in them the appreciation of posture can be completely lost without the appearance of ataxia. This can be explained by the nature of hysteria; because here the disturbance lies in the most central fields of consciousness, so that the intelligent appreciation of passive changes of position is annulled, but not the control of movements, which is supplied by the sensory impulses further down.

Disturbances in the appreciation of passive movements are observed principally in *tabes dorsalis*, where, as mentioned repeatedly above, they furnish a sufficient explanation of the ataxia. It is not rare to meet such disturbances in diseases of the motor area of the cortex, apparently because, for the purpose of coördination, the sensory fibers which subserve the appreciation of posture are anatomically related to the psychomotor centers. The above-mentioned disturbances in the perception of posture which occur in hysteria belong, in a broader sense of the word, as most hysteric symptoms do, to cortical manifestations.

Method of Testing the Touch Perception (the Stereognostic Sense).—Touch perception, *i. e.*, the recognition of the form of objects by their surface, is by no means, as is sometimes supposed, merely a function of the tactile and pressure sensation. Its popular title, feeling sensation or feeling sense, is, therefore, in the strict sense of the word, incorrect. In handling an object we first employ the touch and pressure sense, then the appreciation of the active movements essential to feeling the object, further the perception of the position of the fingers encircling it, and, finally, the sensation of temperature, to recognize the material of which it consists (metal, wood, etc.). Here again it is a question of very complicated perception worked out in the brain with various aids, but in no way the product of a single specific sensibility. This conception makes it clear how, even when the examination of the simple sensory functions (contact, perception, etc.) shows no disturbance at all, the stereognostic recognition of objects may be disordered in cerebral disease, *i. e.*, in lesions of the motor cortex, whose relation to the innervation sense and to the judgment of active and passive movements and of the position of the extremities has already been mentioned (see p. 972), as well as in peripheral motor paralysis, which prevents a correct appreciation of the innervation sense. Conversely, touch perception will be at least impaired where the elementary sensory functions have suffered. Still, this is not always the case because the intelligent individual possesses in a high degree the faculty to replace this defect in the perception through the imagination; in other words, to guess correctly from few guides.

To test the stereognostic sense we ask the patient to close the eyes, and name various small objects placed in his hand. This function is only slightly developed in the feet, yet a healthy individual can recognize larger objects, *e. g.*, the number of fingers with which he is touched, a glass or a bottle even, with them. Objects placed upon the trunk can be recognized only when they are very large and characteristic. This clearly demonstrates that the stereognostic sense is not essentially aided by the cutaneous sensibility, as the old name, "feeling sense," would lead us to believe. As is well known, the stereognostic sense is very acutely developed in the mouth, where it depends considerably upon the perception of the active movements and of the position of the tongue.

PHENOMENA OF SENSORY IRRITATION

Paresthesia.—By paresthesias are understood subjective sensations, *i. e.*, sensations corresponding to no correlation in the external world, which are not actually painful, but which, without any sharp boundary, often merge into pain. They are sufficiently well characterized by such names as "*furry*," "*tickling*," "*crawling of ants*," and "*falling asleep*." The interrupted character and the wide dissociation of these sensations (the latter especially characterizes the sensation of fur or crawling of ants) depend, according to the researches of von Frey, upon the oscillatory character of the nerve stimulation in pressure sensation. This can very easily be demonstrated by exciting the pressure points by irritation hairs. (See p. 968.) Subjective feelings of warmth and cold correspond to similar paresthesias in the province of the thermal nerves; those of smell, sight, hearing, and taste, in the territory of the higher senses. Paresthesias may arise from an irritation of the sensory tracts at any point of their entire course, but they are most frequently observed in lesions of the sensory roots downward, and are, therefore, localized in the peripheral nerves. The paresthesias which occur in spinal cord affections, and which are localized at the intercostal nerves or, rather, their sensory roots, are spoken of as "*girdle sensation*." The girdle sensation frequently becomes a "*girdle pain*." Paresthesias play an especially important part in the obscure clinical picture of acroparesthesia.

Spontaneous Pains.—In a general way pain may be subdivided into parenchymatous and neuralgic pains. In *parenchymatous pains* the sensory fibers are irritated at their outermost terminal ramifications; in *neuralgic pains*, at the trunks of sensory or mixed nerves, in the sensory roots, or in the sensory centers. In the *former* the terminations of the sensory fibers are irritated quite independently of their origin, and, therefore, the pains overlap the boundaries of peripheral sensory areas, apparently at will. *Neuralgic pains*, on the contrary, according to the law of eccentric projection, are localized in areas that correspond exactly to the peripheral distribution of the nerve-trunk or nerve involved. Pain may, however, be felt in neighboring nerve territories as a result of radiation. (See p. 983 et seq., Sympathetic Sensations.) A further difference between these pains is to be found in their severity. *Neuralgic pains* are generally much more severe than *parenchymatous pains*, for the reason that in the former a much larger number of fibers are painfully irritated, and ordinarily at the same moment. Probably for the same reason remissions in a severe pain are more decided in

neuralgic than in *parenchymatous pains*. Some of these remissions can readily be attributed, at least in part, to a fatigue of a central pain-percipient apparatus, a fatigue which naturally occurs sooner and more pronouncedly after intense irritation than after weaker irritation. Another distinction is that, generally, with *parenchymatous pains*, the entire painful area is sensitive to pressure. This is sometimes the case with *neuralgic pains*; but, as a rule, only that portion of the nerve-trunk is sensitive to pressure which lies superficially or upon a hard foundation (*neuralgic pressure points*).

The best-known example of *neuralgia pains* are the *true neuralgias*, which occur in some instances in otherwise healthy individuals, but which in other instances are indirectly due to disease (*articular rheumatism, syphilis, diabetes, etc.*), and the so-called *lancinating pains* in spinal cord diseases, especially in the initial stage of *tabes dorsalis*.

In regard to *parenchymatous pain* we should remember that internal organs which normally do not react painfully to mechanical lesions, may, under pathologic conditions, give rise to pain of the greatest severity. It would seem that, in addition to the pain depending upon irritation of special nerves for pain, which the author prefers to call *physiologic pain*, and which, for teleologic reasons, is limited merely to the body surface, there is a second sort of pain which depends upon the increased irritability of nerve-tracts not capable of producing pain normally. This conception involves the further assumption that certain sensory nerves not usually transmitting pain (*e. g.*, the optic and acoustic) may, under strong stimulation, also become distinctly painful; and that this kind of severe sensory irritation is not simply a secondary effect caused by reflex muscle contraction (*iris, stapedius*,¹ etc.).

To the *parenchymatous pains* belong most of those *pains* which occur in *organic disease of various viscera*; many of the *diffuse headaches* of *meningitis* and *intracranial pressure*; *toxic, febrile, dyspeptic, and anemic headaches*, as well as *migraine* and most forms of *neurasthenic headaches*.

The author does not accept the view that internal headache must always have its origin in the *dura mater*. In a *physiologic* sense the *intracranial parts* suffer pain merely from mechanical lesions of the *dura*; but the brain may behave just the same as many internal organs (*gall-bladder, heart, etc.*), namely, while possessing physiologically no deep pain perception, it becomes sensitive to pain under the influence of pathologic conditions. The author does not doubt that the fatigue headache of *neurasthenia*, just as well as the pain of *migraine*, is a cerebral pain, and this view is supported by the occurrence of the *scintillating scotomata* in *migraine* (see p. 1034), which are unquestionably localized in the brain cortex.

In most cases the sensation of pain, whether it be *neuralgic* or *parenchymatous*, is of peripheral origin, *i. e.*, depends upon an irritation of the peripheral sensory neurons (of the peripheral nerves or sensory roots). It still seems doubtful whether pains may be caused by involvement of the conduction tracts above the sensory roots in the spinal cord. This part of the conduction pathway has usually been considered to be purely *esthesodic*, *i. e.*, conductory but not irritable. On the contrary, *eccentrically projected pains* can doubtless be produced by lesions of the sensory tracts in the brain, especially of the most poste-

¹ [The recent studies of Ramsay Hunt (*Archives of Otology*, 1907, vol. xxxvi, No. 4) on the cutaneous distribution of the *pars intermedia* of Wrisberg, the intimate connections between the acoustic and geniculate ganglia, and their relations to herpes zoster of this region, should make us cautious in accepting this view of the acoustic nerve.—ED.]

rior part of the internal capsules,¹ as recently observed by the author in a case of hemiplegia.² It is also certain that pains may take their origin from the most central organs of perception. It is to this category that the *suggested* and *autosuggested* pains and certain *hysteric pains* belong. Naturally, these pains have in their distribution the character of parenchymatous not neuralgic pains, because the arrangement of the elements in the central parts does not correspond to the nerve-trunks, but to the limits of the organ. For instance, hysteric joint pains are often improperly spoken of as articular neuralgia.

A peculiar combination of symptoms, so-called *anæsthesia dolorosa*, should be mentioned here. It consists of the occurrence of spontaneous pains in a portion of the body which is anesthetic to external stimulation. Such conditions occur when a focus of disease, most often of the peripheral nerves or nerve-roots, interrupts the conductivity of peripheral stimuli and at the same time causes irritation of the sensory fibers. This symptom-complex is seen most frequently in tumors of nerves, but it also includes many of the pains of tabes dorsalis and neuritis.

Hyperalgesia (Hyperesthesia); Tenderness to Pressure.—By the term hyperesthesia or, better, hyperalgesia, we understand a condition of the sensory mechanism in which stimulation produces the sensation of pain in a certain area (especially of the skin), although normally such stimulation would not be painful. The slightest touch of the skin, moving the part, or the mildest sort of thermic influence may, under such circumstances, produce pain. We now recognize that pain perception (at least cutaneous pain perception) is a specific performance of a definite kind of nerve-fibers (see p. 970, note 2); hence, we may regard hyperalgesia merely as a supersensitiveness of the pain nerves. We have as yet no convincing demonstration that a vigorous stimulation of other sensory qualities, *e. g.*, of touch, warmth or cold, can produce pain, because we cannot exclude a coincident implication of the pain nerves in every such vigorous stimulation. Therefore, we should substitute the expression hyperalgesia for hyperesthesia. That hyperalgesia of the lower half of the body appears most readily on the same side as the lesion in spinal hemiplegia must be explained by the supposition that in pathologic conditions the pathways of other sensations, especially that of touch sense, may also give rise to painful stimuli. This occurs either by means of increased excitability of the pathways (see p. 981), or else through a narrowing of the channel for the centripetal conduction of sensory impulses, as in the author's explanation of hyperalgesia in spinal hemiplegia. (See p. 1126.) We do not yet know what sort of injury to the pain-conducting or the pain-appreciating parts of the nervous system can give rise to the usual form of hyperalgesia; but it is certain that peripheral as well as central parts may assist in this hyperalgesia, from an associated involvement of the sensory fibers or cells. Such involvement produces slight injuries, which are insufficient to induce anesthesia, but sufficient to cause irritation. The best known examples are the *hyperalgesias in the domain of neuralgic nerves during the early stages of neuritis*, the *zone-like hyperalgesias of the upper borders of sensory dis-*

¹ See the meager literature upon this point in the article of Alfred N. Reichenberg, *Zeit. f. Nervenheilk.*, vol. xi, pts. 5 and 6, p. 349.

² [This is also the chief symptom in Déjérine's thalamic syndrome.—Ed.]

turbances in cross-lesions of the spinal cord, the above-mentioned unilateral hyperalgesias in spinal hemiplegias (see p. 1126), and the general hyperalgesia of hysteric or neurasthenic patients.

The so-called *tenderness to pressure* (better described as increased sensitiveness to pressure) is in reality nothing more than a special form of hyperalgesia. In the examination of the nervous system, the pain sensitiveness of the nerve-trunk to pressure which occurs principally in peripheral neuralgic and neuritic affections is of special interest. It is under some circumstances essential to examine into this phenomenon, even where no spontaneous pain is present.

The hyperalgesic zones of the skin in diseases of the viscera are mentioned in the following section.

Sympathetic or Reflex Sensation; Irradiation of Pain; Tickling; Hyperalgesic Zones of the Skin in Diseases of the Deeper Organs.—So-called sympathetic or reflex sensation is clearly related to hyperalgesia.

The best-known form of this is pain irradiation, in which the pain is perceived far beyond the limits of the painfully irritated peripheral part (pain in the entire trigeminal distribution, occasioned by a single carious tooth). This phenomenon can be explained only by assuming that the painful stimulation in the central organs (spinal ganglia, gray substance of the spinal cord or of the brain) overlaps or radiates to neighboring tracts by means of dendrites and Golgi's collaterals, and that, in accordance with the law of eccentric projection, confusion as to the origin of the perception results.

The pain sense is not always concerned in reflexes either of primary or of secondary nature; in fact, touch and temperature sense or the higher senses can produce them, and such sympathetic sensations are not necessarily painful.

As an example of such associate sensation *tickling* may be cited. This is an irradiating or sympathetic sensation of an oscillating character, diffused over a considerable surface of the skin, caused by a circumscribed skin stimulation.

Quinke¹ has made quite a complete collection of the practically important sympathetic sensations which have been thus far determined; but only a few of the most important will be mentioned: trigeminal neuralgia in affections of the frontal sinuses; parietal pain in affections of the middle ear and of the mastoid process; a tendency to cough from irritation of the posterior wall of the auditory canal (irradiation from the auricular branch of the vagus to the other vagus branches); a marked sensation of tickling and shuddering in biting upon sand; painful sensation in the back in swallowing the wrong way; laryngeal pain in percussing a pulmonary abscess (Quinke); pain in the left arm (rarely in the right) in angina pectoris; pain in the back in stomach diseases; feeling of tickling in the nose from intestinal worms; pain in the shoulder in liver affections; pain in the left shoulder in affections of the spleen; pain in the back and genitalia in renal affections; pain in the lumbar region and genitalia in bladder affections; pain in the epigastrium and the stomach region in endometritis and during menstruation; pain in the knees in coxitis; simultaneous polyesthesia (p. 969) in spinal cord affections.

Fig. 380.—Diagram to illustrate skin hyperalgesias and the radiation of pain in disease of deeply situated organs.

¹ Zeit. f. klin. Med., 1890, vol. xvii.

Fig. 381 —For description see Fig. 382.

A phenomenon related to and frequently associated with these sympathetic sensations—a circumscribed cutaneous hyperalgesia depending upon diseases of the deeper organs—is of more diagnostic significance. The best-known example is the sensitiveness to pressure of the skin of the precordia in heart disease. This hyperalgesia is perhaps most satisfactorily explained thus: The centripetal irritations proceeding from the diseased organs which escape direct perception, stimulate by irradiation the neighboring sensory parts of the central organ, which are inter-

Zones on the trunk and extremities: Diseases of the heart, pain, and hyperaesthesia in zones, C_3 ,¹ D_1 , D_4 ; tuberculosis of the lungs, D_1 - D_7 , particularly D_2 , D_3 , D_5 ; diseases of the esophagus, particularly D_1 , D_4 , D_9 ; diseases of the breast, D_4 , D_5 ; diseases of the stomach, D_7 , D_8 , D_9 ; diseases of intestine (pylorus, colon), D_{10} , D_{11} , D_{12} ; diseases of liver, D_7 , D_8 , D_9 , D_{10} ; diseases of the kidney and ureters, D_{10} , D_{11} , L_1 ; diseases of the bladder, S_1 , S_2 , S_4 ; diseases of the ovaries and testicles, D_{10} ; diseases of the uterus, D_{10} , D_{11} , D_{12} , L_1 ; diseases of the cervix, S_1 , S_2 , S_3 , S_4 (after H. Head).

¹ See Fig. 383.

sections for the sensory paths of the corresponding cutaneous surfaces, and thus cause the latter to appear hyperalgesic. In contrast to actual sympathy or irradiation, this radiated stimulation is not strong enough to be appreciated by the sensorium as pain, but is merely sufficient to cause hyperirritability of the sensory conductions coming from the skin.

Fig. 383.—Hyperalgesic and radiation zones of the skin in diseases of deeply situated organs. Zones on the head and neck: Nasofrontal zone, diseases of the eyes, nose, and upper incisors; middle orbital zone, in hypermetropia; temporofrontal zone, diseases of the ears and heart; temporal zone, in glaucoma (after H. Head).

Sincipital zone: Diseases of the middle ear.
Parietal zone: Diseases of the ear and stomach.

Occipital zone: Diseases of the posterior half of the larynx and certain abdominal viscera.

Maxillary zone: Diseases of the iris and vitreous body.

Mandibular zone: Diseases of the upper molars.

Nasolabial zone: Diseases of the nose and dental pulp.

Mental zone: Diseases of the incisors and canines.

Hyoid zone: Diseases of the tonsils, tongue, and lower molars.

Upper laryngeal zone: Diseases of the dorsal surface of the tongue and the wisdom teeth.

Lower laryngeal zone: Diseases of larynx.

Fig. 380 explains the process diagrammatically: *a* Represents the diseased organ with a centripetal stimulation proceeding to a sensory station, (*b*) for example, in the spinal cord; from there the stimulation can come to the sensorium (*c*), either directly (*b-c*) or indirectly (*b-d-f*), jumping to a neighboring sensory tract (*e, f*). If

this process of irradiation produce a painful stimulation at *d*, a painful sympathetic sensation will be referred to the cutaneous area (*e*); whereas if it produce merely a hyperirritable condition at *d*, the cutaneous area (*e*) will present a hyperalgesia to pressure and to other stimulations not usually causing pain. Thus, circumscribed cutaneous hyperalgesias, if anatomically established, may, under some circumstances, possess the same diagnostic value as actual sympathetic sensations.

Head, of London, has taken pains to investigate these zones of cutaneous hyperalgesia in a great number of pathologic conditions in order to establish some diagnostic relations to deep-lying diseases. Corresponding to the above explanation, he found that the hyperalgesic zones were identical with the zones to which the irradiation pains were projected in the diseased organs in question. He tabulated his observations in the accompanying plates (Figs. 381, 382, and 383). The separate zones are shaded differently. The numbers and letters refer to the segments of the spinal cord (designated according to the corresponding spinal nerves) whose stimulation is the cause of the cutaneous hyperalgesia (based upon our knowledge of the spinal sensibility topography of the skin (see p. 1143 et seq.). Probably the affected organs are also supplied by the same nerves. Thus far no satisfactory anatomic explanation has been able to correlate the localizations of hyperalgesic zones of the head to definite diseases.

Though interesting theoretically, Head's statements need further confirmation and perhaps modifications. Such relations of the deeper organs to the surface of the skin make one appreciate the therapeutic action of counterirritation to the skin, especially upon deep-seated pains. It is only fair to suppose that the same anatomic tracts which conduct the cutaneous hyperesthesias in diseases of the deeper organs can be utilized to transmit inhibition of pain by vigorous stimulation of the skin.

IV. EXAMINATION OF THE REFLEXES¹

In testing reflexes it is advisable to distract the patient's attention as much as possible from the parts under examination, otherwise an involuntary inhibition may alter the reflex. The simplest device is to direct him to close his eyes. The fatigue of a reflex is sometimes responsible for mistakes in diagnosis. The response to the first tap should be observed attentively, because it may disappear after one or two repetitions. If the first response had not been noticed, the examiner would then incorrectly consider the reflex absent. It is, therefore, a safe rule to observe each reflex quickly and accurately, and to utilize repeated, careful examinations in order to discriminate in any doubtful case, for reflexes, like other nervous functions, often vary at different times. These precautions are especially valuable in testing the patellar reflex, which is so important in diagnosis.

Ordinarily, the reflexes are local in character, *i. e.*, they take place in the region of the body that is irritated. But with an increase in the reflex irritability, which may be partly within the normal physiologic limits and depend partly upon reflex stasis (described upon p. 994), the reflexes may be diffused in cross and longitudinal directions to other muscle areas and to other extremities. This corresponds to Pflüger's laws of reflex dispersion.

Increase of the reflexes, as well as decrease or absence and qualitative abnormalities (the so-called pathologic reflexes), are of considerable importance for diagnosis.

NORMAL CUTANEOUS REFLEXES

The cutaneous reflexes of the upper extremities and of the face are very inconstant. They have, therefore, no diagnostic significance

¹ The reflex belonging to the cranial nerve territory will be described more fully in the special part devoted to examination of the separate cranial nerves. (Concerning the bladder and rectal reflexes, see the section upon Examination of the Bladder and Rectal Functions.)

except when decidedly increased. The following cutaneous reflexes are clinically the most important:

Plantar Reflex.—Tickling or pricking the sole of a healthy person's foot produces a plantar flexion of the toes. (See Fig. 384.) A stronger irritation produces a dorsal flexion of the toes, combined with a dorsal flexion of the foot and flexion of the knee and hip-joints.

The **cremaster reflex** is elicited when the inner surface of the thigh is irritated by scratching or pricking, or by stroking it quickly with the handle of a percussion hammer or some similar object. It consists of a sudden contraction of the cremaster muscle, which draws up the testicle. This reflex should not be confused with the slow, worm-like contraction of the tunica dartos, which frequently follows uncovering the patient, as a result of cooling.

The **inguinal reflex** (oblique reflex) (K. Geigel¹) can be elicited in both sexes by an irritation similar to that described for the elicitation of the cremaster. It consists of a contraction of the lower fibers of the internal oblique muscle above and along Poupart's ligament. Since the cremaster muscle is nothing but a bundle of the internal oblique passing with the testicle through the inguinal canal, the cremaster reflex in reality belongs to the inguinal reflex. Examination of the latter in the female sex takes the place of that of the cremaster reflex.

The **abdominal reflex** is produced by tickling, scratching, or pricking the skin of the abdomen. It consists in a simultaneous contraction of the transverse oblique and recti muscles of the abdomen, which produces a depression of the abdomen and a pulling of the navel toward the side stimulated. While obtaining the reflex, it is better to divert the patient's attention and have him avoid all voluntary tension of the abdomen.

Several abdominal reflexes may be differentiated upon each side of the abdomen—a superior, median, and inferior. Stroking the abdominal wall in a horizontal direction in the region of the epigastrium, mesogastrium, or hypogastrium causes reflex contractions of the abdominal muscles, which remain localized at approximately the height of the stimulation. If, on the contrary, the entire length of the abdomen be stroked in a vertical direction, the whole half of the abdomen is contracted, and the maximum of the excursion is found at the height of the navel. This is what we ordinarily call the abdominal reflex. With more vigorous irritation, horizontal stroking of the abdomen can produce the general abdominal reflex. Strümpell has called attention to the loss of the abdominal reflex on both sides as an important and early sign of multiple sclerosis, and therefore valuable for differentiating it both from pure spastic spinal paralysis and from functional diseases. Jamin has noted the loss of the abdominal reflex on one side in acute inflammatory abdominal affections, *e. g.*, perityphlitis. The most probable explanation of this phenomenon is that it is the result of the voluntary, instinctive and reflex permanent contraction of those muscles directly over the painful part (muscle on guard).

The **interscapular reflex**, which is elicited by stroking the inner edge of the scapula, consists in an adduction of the shoulder-blade. It is frequently absent.

The **gluteal reflex**, a contraction of the gluteal muscles produced by an irritation of the skin about the gluteal region, is also inconstant.

Anal Reflex.—Irritation of the skin of the anus, as by a pin-prick, elicits a contraction of the external sphincter. It is often absent. (Consult p. 995 et seq. and p. 1151 et seq. in regard to the diagnostic significance of abnormalities of the cutaneous reflexes and their localization in the spinal cord segments.)

¹ Deut. med. Woch., 1892, vol. viii, p. 166.

NORMAL TENDON, PERIOSTEAL, AND JOINT REFLEXES

The **patellar reflex**, or the "knee phenomenon," consists in a contraction of the quadriceps extensor excited by a blow upon the patellar tendon. We may employ the ulnar edge of the hand or, better, the edge of a firm, not too light object, *e. g.*, a percussion hammer.

The **Achilles-tendon reflex** consists in a contraction of the calf muscles excited by a blow upon the Achilles tendon. Another method of exciting this reflex is to increase suddenly the tension of these muscles by a passive dorsal flexion of the foot. If the reflex be increased, the latter method causes a series of rapidly succeeding plantar flexions of the foot, which often persist as long as dorsally directed pressure is exerted upon the ball of the foot. The repetition of the flexions apparently depends upon the fact that each contraction of the calf muscles temporarily removes the pressure upon the plantar surface, so that the pressure acts later as a renewed blow. We call such an increase of the Achilles-tendon reflex "the foot phenomenon," "foot-clonus," or "ankle-clonus."

The **tendon reflexes** of the upper extremities are rather inconstant. In healthy individuals a flexion of the hand can sometimes be obtained by striking the flexor tendons at the wrist-joint, a bending of the forearm from the biceps tendons, or an extension from the triceps tendons. If the reflexes be increased, a similar result can be obtained, even in the upper extremities, by striking almost any of the tendons. Sometimes an actual clonus can be produced by vigorously flexing the hand dorsally, "hand-clonus" (analogous to ankle-clonus).

Periosteal and joint reflexes are produced by striking various bony prominences and joints. They are inconstant in health. The best-known periosteal reflexes are those of the ulna and the radius at the wrist-joint. On testing the latter, flexion and pronation of the hand and flexion of the fingers usually appear.

In testing tendon and periosteal reflexes it is especially important to observe the caution enjoined above, that is, to distract the attention of the patient from the part of the body to be examined, since otherwise, through involuntary tension of the muscles in question, the reflex may be inhibited. A very good plan is to interest the patient in some subject, and to engage him in conversation while you are testing. Jendrassik's device for reinforcement is often very successful in testing the tendon reflexes of the lower extremities. The patient is directed to lock his fingers and pull strongly, as if tearing them apart, but without separating them. Not infrequently, however, this reinforcement does the opposite to what it usually accomplishes, *i. e.*, it weakens or inhibits the patellar reflex, probably because, instead of actually concentrating his entire attention and effort upon the fingers, the patient renders the muscles of his lower extremities tense by associated movement, and so inhibits the patellar reflex. Another precaution that should always be taken is to be sure that the muscles concerned in the reflex are actively relaxed, but passively tense. This is especially important in testing the patellar reflex. For the latter, the sitting posture is most desirable, with the leg to be examined crossed and hanging limply over the other. In bed-ridden patients the leg is supported below the knee by the hand of the examiner in semiflexion.

CONSTANCY (i. e., FREQUENCY) OF OCCURRENCE OF THE NORMAL SPINAL REFLEXES

Of the above-described reflexes, there are only a few which are fairly constant, and even these not absolutely. Some are even present only in a minority of cases. According to the researches of Pflüsterer,¹ the reflexes are found as follows:

MALES

<i>Epigastric reflex</i> (upper abdominal wall reflex).....	present in 62 per cent. ²
<i>Abdominal reflex</i> (middle abdominal wall reflex).....	" " 99 "
<i>Cremaster reflex</i>	" " 66 "

The foregoing shows that the absence of the reflexes printed in italics only is of diagnostic value.

RECENT VIEWS CONCERNING THE PHYSIOLOGIC ORIGIN OF THE REFLEXES AND THEIR ALTERATION IN PATHOLOGIC STATES.—BLOCKING OF THE REFLEXES

Formerly it was believed that the spinal cord was the center of all reflexes. This view was based upon the results of animal experiments and upon the observation that most transverse lesions of the cord were associated with increase of the reflexes. Modern neuropathologists, however, following the teaching of Bastian, endeavor to dethrone the cord from its position as a reflex organ in man. Bastian and others have shown that all the reflexes were found to be completely abolished in some cases in which there is complete transverse lesion of the spinal cord. It was, therefore, argued that no transverse lesion could be complete if the reflexes in the region innervated below the injury either persisted or were increased. A few such observations, however, proved nothing, because the part of the spinal cord situated below the obstruction might be affected in such cases by inhibition or by a diminished blood-supply conditioned by lesion of the spinal arteries.³ In order to determine whether the reflexes of clinical importance have their centers in the spinal cord, it is much more essential to inquire whether there have been cases with persistent reflexes of the lower extremities in which a careful anatomic examination has shown postmortem complete cross-section of the spinal cord. In recent years such cases, absolutely free from question, have been described,⁴ and show, beyond doubt, that the

² The author regards this as too low.

³ Gerhardt, *Ueber das Verhalten der Reflexe bei Querdurchtrennung des Rückenmarkes*, *Deut. Zeit. f. Nervenheilk.*, 1895, vol. vi, p. 127, and Jendrassik, *Ueber die allgemeine Localization der Reflexe*, *Deut. Arch. f. klin. Med.*, 1894, vol. lii. ⁴ *Ibid.*

tendon reflexes, at least, are independent of nervous mechanism beyond the spinal cord. Similar results have been proved by the persistence of the tendon reflexes after decapitation (Laborde).¹ Hence it is plainly incorrect to maintain that all reflexes require the aid of the brain.² The discussion has been valuable in more accurately determining the merits of the earlier conception, which argued that all reflexes took place in the spinal cord and homologous portions of the brain stem. In this connection Jendrassik has formulated a theory of the reflexes which is based upon clinical evidence and which is worthy of careful study. [See also upon this subject, Collins and Fränkel, *Muscle Tonus and Tendon Phenomena*, Medical Record, December 12, 1903.—ED.]

According to Jendrassik, there are spinal and cerebral reflexes, as well as a combination of the two, *i. e.*, reflexes requiring both cerebral and spinal center for their normal occurrence. He subdivided the physiologic reflexes and characterizes them as follows:

I. Spinal Reflexes.—This division includes *tendon, periosteal, and joint reflexes*. Their characteristics are as follows: 1. They are generally discharged from parts which possess little sensation. 2. The reflex is associated with no particular feeling. 3. The discharge takes place by means of a simple mechanical irritation, such as a blow, etc. 4. The intensity of the reflex depends upon the degree and not upon the duration of the irritation. 5. The reflexes are quite as easily excited in ourselves as in others. 6. The latent time of the reflex, corresponding to its origin in the spinal cord, is the shortest. 7. The ensuing movement is a very simple one, and serves a recognizable purpose. 8. Making other muscles tense increases the reflex (reinforcement method of Jendrassik; see, however, p. 989). 9. Delay of these reflexes never occurs pathologically. 10. Psychic influences have no effect upon these reflexes aside from distraction of attention, which increases them.³

II. Cerebral Reflexes.—These are, to a large extent, the cutaneous reflexes. The scapular, abdominal, cremaster, gluteal, plantar, eyelid, palatal, conjunctival, and anal reflexes belong to this group. Their characteristics are as follows: 1. They are discharged from sensitive spots which are not ordinarily accustomed to a light touch (tickling). 2. The liberation is associated with a specific sensation (prickings, cold, tickling, etc.). 3. Brief stimulation is efficacious for their liberation, just as it is for the spinal reflexes described in the previous paragraph. 4. A light touch has often a more vigorous action than a stronger one; individuality has a decided influence. 5. These reflexes can scarcely ever be liberated by the person himself, and then only very slightly. 6. The latent time is longer and not so constant as with the spinal reflexes. It is quite dependent upon the sensation time and corresponds to the reaction time, *i. e.*, the time which the voluntary reaction demands of a sensory stimulation. 7. The resulting movement is simple, and its principal characteristic is that it shows an effort to escape from the irritation. 8. Increased activity of the other muscles never increases the reflex, but may even diminish it. 9. These reflexes are diminished on the paralyzed side in cerebral hemiplegia. 10. They are delayed in cases of delayed sensation. 11. Psychic influences can either diminish or increase these reflexes; distraction of the attention impairs them.

III. Complex Reflexes.—To this group belong reflexes which have complicated "centers" within which the reflex occurs, not as a single movement, but as a series of such, *e. g.*, sneezing, vomiting, swallowing, coughing, urinating, defecating, genital reflex (ejaculation). The characteristics in common are as follows: 1. They are liberated from very sensitive places. 2. The liberation takes place with a specific sensation which plays even a greater rôle in the origin of the reflex than in those of the cerebral group. 3. The liberation requires protracted stimulation. 4. Individuality has a great influence upon the occurrence of the reflexes. 5. The stimulation which produces these reflexes is a specific and complicated one. 6. The

¹ Quoted by Jendrassik.

² According to Bastian's and Jackson's view, especially of the cerebellum. The author believes that the cerebrum is still more essential.

³ The author has found that psychic excitement considerably increases tendon reflexes and this increase may serve as an important sign of states of psychic excitement.

latent time is longer than for any of the other reflexes. Their liberation seems to require a sort of summation of stimuli. 7. The resulting movement is very complicated and bilateral; several muscle groups take part, and in some of them the reflexes act antagonistically. 8. Muscular activity weakens their effect to some extent. 9. Psychic influences produce a great effect. 10. Reflexes of this group belong to the vegetative functions.

The distinction between Groups III and II is essentially this: in the latter the sensation is transposed directly into simple reflex movements; whereas in the former, the sensation, *i. e.*, the cortical stimulation, first of all excites a complicated reflex center of activity. This center is composed of several distinct centers, and within the main center the reflex process then takes an independent course. Should this subdivision be accepted, the author would call attention to the fact that the peculiarities stated by Jendrassik as characteristic of the individual groups do not always materialize. It would lead us too far, however, to discuss these points in detail. For the last group of Jendrassik the author would suggest the name of corticonuclear reflexes. Those which also involve spinal areas of innervation might with equal propriety be designated as cerebrospinal reflexes. In the individual corticonuclear reflexes the cerebral factor plays a varying but important part, as is shown by the fact that completely unconscious individuals never cough nor sneeze, but, on the other hand, they can, under some circumstances, still swallow and urinate and defecate normally, even if unwittingly.

Various examples might be added to show how dependent the reflexes of Groups II and III are upon the cerebrum; but the author will allude only to the following: the diminution of the cutaneous reflexes over the anesthetic area of the hysteric; the purely cerebral origin of the plantar reflex in ticklish persons, in whom it may be elicited by threatening to tickle them, even without touching them; and the occurrence of vomiting evoked by some disgusting conception.

Recognizing the above theories of the origin of reflexes, we should now attempt to explain their clinical manifestations under pathologic conditions, especially in the case of an interrupting focal lesion of the brain and spinal cord.

Cerebral Hemiplegias.—The tendon reflexes are here, as a rule, preserved, because they come under Group I (the spinal). In the beginning they may be lost, presumably on account of the inhibiting action of the lesion, but later they are usually increased, because of the complete abolition of cerebral inhibition. (See p. 952 et seq., Active Contractures.) The behavior of the cutaneous reflexes (Group II) in cerebral hemiplegia is explained by the supposition that the voluntary tracts (pyramidal tracts) are identical with the motor limb of the cortical reflex arc. We therefore generally find upon the paralyzed side diminution or disappearance of the cutaneous reflexes (p. 991, Group II), because its reflex arc is interrupted. In hemiplegia of indirect origin, *i. e.*, when the lesion is not immediately of the pyramidal tract, the cutaneous reflexes may be retained, although they, too, are in the beginning usually diminished. This is explained by the supposition that the lesion here does not permit the passage of the voluntary impulse, while it offers no obstacle to the reflex impulse. The persistence of the cutaneous reflexes upon the hemiplegic side can be regarded as a favorable prognostic sign, because it argues for an incomplete interruption of the motor tract. The behavior of the complicated reflexes (Group III) in cerebral hemiplegia depends upon the varying degree of influence which the cerebral factor has upon their origin. As a general rule, they are not affected, because they are bilaterally innervated.

Transverse Lesions of the Spinal Cord.—If Jendrassik's conception be correct, the tendon reflexes must in general be considered pure spinal reflexes, and the cutaneous, on the other hand, cerebral reflexes. Clinical experience does not seem to coincide perfectly with this conception, for we ordinarily find both the cutaneous and the tendon reflexes increased in transverse spinal cord lesions, such as those caused by myelitis. How is this to be explained. The persistence of the tendon reflexes is clear enough, and their increase is easily explained by supposing that the inhibitory fibers running in the affected pyramidal tracts have been cut off; but how can we explain the increase of the cutaneous reflexes, if, as Jendrassik assumes, they really have their reflex arc in the brain? Jendrassik considers that these reflexes, which in transverse cord lesions are ordinarily regarded merely as accentuated cutaneous reflexes, are in reality pathologic cutaneous reflexes, which normally do not occur in this shape at all, but in transverse lesions take the place of the normal cutaneous reflexes which have been destroyed. He offers the following arguments in support of this theory. The normal cutaneous reflexes of the lower extremities can be elicited only from the sole of the foot, no matter how vigorous the stimulation may be; while the pathologic cutaneous reflexes in cross-

lesions of the cord can be elicited by irritating almost any part of the lower extremities. The normal plantar reflex depends upon a sensation of pain and tickling, and the time of its appearance upon the occurrence of such sensations (best recognized in the delayed transmission of pain in *tabes dorsalis*); the pathologic reflexes, on the contrary, are neither connected with nor dependent upon sensation. The physiologic reflex exhausts after repeated testing, even though it is very vigorous; whereas the pathologic reflex never exhausts; it can be elicited again and again. A light touch will very easily stimulate the physiologic cutaneous reflex; whereas the pathologic reflex is in direct ratio to the intensity of the irritation. The pathologic cutaneous reflex of the lower extremity always consists of a maximum flexion of the thigh, outward rotation of the knee, and the dorsal flexion of the foot (in rare instances the reverse, *i. e.*, an extension of the thigh and plantar flexion of the foot). Both of these types are very different from the physiologic reflex, which is essentially a movement of escape, and consists of a plantar flexion of the toes and a dorsal flexion of the foot, accompanied by a very slight movement of the muscles of the thigh and pelvis. Jendrassik explains the appearance of these vigorous abnormal reflexes of transverse cord lesions in the place of the normal by assuming that the sensory impulses which are cut off at this point of the lesion make for themselves a sort of lateral path which is not normally in use. There are cases of acute transverse lesions of the cord in which the cutaneous reflexes are diminished instead of increased. In them he assumes that the lower part of the spinal cord is also affected, so that these pathologic reflexes cannot take place perhaps because of an anatomic lesion (deficient blood-supply), or perhaps on account of an inhibitory influence by the lesion. A similar explanation will account for the loss of the tendon reflexes which we see so often in acute traumatic complete transverse division of the cord. The increase of the tendon reflexes, and the appearance of the pathologic cutaneous reflexes which is observed later in the course of these cases, are sufficient evidence to support such an explanation.

Jendrassik's theory of the genesis of the reflexes has many arguments in its favor, but in the author's opinion is very weak in one point—the supposition that in transverse lesions of the cord the reflexes which belong to parts supplied by the lower portion of the cord are not the ordinary retained reflexes, but pathologic reflexes of newly opened pathways. This assumption seems permissible in the case of the vigorous and altered reflexes of the lower extremities, as they were described above. But should the cremaster and abdominal reflexes, etc., be preserved in a myelitis of the upper dorsal cord with complete motor and sensory paralysis, it compels us to assume that such circumscribed reflexes must arise by a path other than the physiologic, and that in such complete paralysis the physiologic cerebral reflex is cut off. The persistence of these reflexes, whether weakened, normal, or increased (any one of these conditions is possible in transverse lesions), is most readily explained by assuming that their center or, better expressed, their reflex arc lies below the transverse lesion, and is thus preserved. On the other hand, the absence of these reflexes in cerebral hemiplegias seems difficult to reconcile with such a supposition. The following theory will, the writer believes, clear up the difficulty: The cutaneous reflexes which Jendrassik considers to be purely cerebral are in reality like his third group (p. 991), corticonuclear, *i. e.*, cerebrospinal in so far as they belong to spinal areas. They have a reflex center or, better,¹ a lower short reflex arc in the cord, and, furthermore, a more highly differentiated “upper” reflex arc in the brain. In a sense they possess two collateral reflex arcs. (See Fig. 464, p. 1151.) Under ordinary circumstances an accompanying excitation of the cerebral arc is essen-

¹ Compare p. 1151 et seq., Segmental Localization. The expression “reflex center,” employed merely for the sake of brevity, is inaccurate and incorrect, and the conception according to which it was first used is no longer tenable.

tial to the operation of the reflexes. This arc, when so stimulated, transmits a centrifugal impulse to the spinal reflexes. In a motor hemiplegia of cerebral origin the lesion (*a b*, Fig. 464) interrupts the centrifugal tract from the brain to the spinal reflex center (this tract is either identical with or situated very near to the pyramidal tract). Hence the cutaneous reflexes upon the paralyzed side disappear. In a transverse lesion of the cord (*c d*, Fig. 464) the cerebral reflex arc is also interrupted, and one would naturally expect a similar disappearance of the cutaneous reflexes; but this does not occur, because the lesion, by interrupting the sensory conduction in the cord, in a measure dams the sensory stimulation. Therefore, the peripheral impulse must find a path in the region of the lower cord segments. It generally selects the customary path, *i. e.*, the formed spinal reflex arc of the corresponding cerebrospinal reflex, and so the cutaneous reflexes become purely spinal.

This explains how many of the preserved reflexes, *e. g.*, the abdominal cremaster, retain their complete physiologic distribution. It also explains how other reflexes, by means of the damming up of exciting impulses at the lesion, attain both abnormal intensity and distribution by transmission of the impulse to neighboring paths. (Jendrassik's Pathologic Reflexes, see p. 997 et seq.)

The stasis of the excitation at the level of the lesion is sufficient to account for the abnormal intensity of the reflexes in transverse lesions, even without the assumption of abolition of the reflex inhibitory tracts (although the latter shall not be contested).

On the other hand, in cerebral hemiplegia, since extensive by-paths in the whole cord and a great part of the brain are open to centripetal excitation (Fig. 464, lesion *a b*), there is no reason for an actual stasis, and likewise no ground for assuming a pure spinal origin of reflexes which otherwise come from the brain. These, therefore, from lack of cerebral excitation, disappear, or, through insufficient exertion, appear weak. Perhaps we can assume that the centripetal impulses here are dispersed so completely through the wide-open tracts of the nervous system that they become inert and run, like a lightning-rod, into the ground. The author can claim more than a mere diagrammatic representation for this theory of damming back and jumping over of sensory irritation in the cord, because Golgi has demonstrated the existence of branched sensory collaterals (Fig. 464), and has shown that paths for discharge are open upon all sides, and that it depends only upon the intensity of the resistance which of these pathways will be selected by the stimulation, *i. e.*, the reflex. The diminution of the reflexes sometimes observed in very acute, especially traumatic, cord affections is, according to this theory, to be attributed to inhibition or to injury of the lower cord segments from circulatory disturbances, etc. The behavior of the function of the bladder and rectum according to this conception will be discussed later. (See p. 1162.)

The author's theory, contrasted with Jendrassik's, simplifies the scheme of the reflexes. We should differentiate physiologically between only two groups of reflexes. The first group would comprise *purely spinal* or, better, *purely nuclear* reflexes, because some of them occupy the region of the cranial nerves, and would include the tendon, periosteal, and joint reflexes. The second group, the cerebrospinal, *i. e.*, cerebronuclear, reflexes, would include both the normal, simple, cuta-

neous, and mucous membrane reflexes and the complicated reflexes of Jendrassik's third group—bladder, rectal reflexes, etc. In the second group the brain and spinal cord (or the cerebral cortex and cranial nerve nuclei) act normally together, *i. e.*, the activity in a lower (nuclear) reflex arc is, under physiologic conditions, discharged by the cortex. In transverse lesions of the cord, reflexes of this second group may be originated exclusively by way of the spine, and so be increased or even deformed by reflex damming. This conception seems to the author the only one which corresponds to our clinical experience. That of Jendrassik is essentially opposed to the facts, inasmuch as it does not recognize the short spinal path for normal cutaneous reflexes which has been localized by pathologic and experimental findings (see Table upon p. 1153 et seq.), and which is made use of for the purpose of local diagnosis. Their existence is shown by the occurrence of undeformed reflexes in total transverse lesions of the spinal cord.

DIAGNOSTIC AND PROGNOSTIC SIGNIFICANCE OF QUANTITATIVE ALTERATIONS OF THE REFLEXES

The demonstration of the presence of a reflex is of greater diagnostic significance than the demonstration of its absence or diminution, because its presence is conclusive evidence of an intact reflex arc; whereas, although its absence or diminution may mean that the arc is interrupted, it may also mean that the reflex is affected by a mere inhibition or by remote influence from some circulatory disturbance. Similarly, an increase of a reflex is ambiguous. The latter may be caused by lesions which directly stimulate the reflex centers or tracts, or by those which remove inhibition or injure inhibitory tracts. The pathologic relations of the reflexes are, therefore, evidently complicated. Only a comparatively few types will be mentioned.

The relation of altered reflexes to lesions which are situated in the lower (nuclear) reflex arcs is perhaps the most distinct. (See p. 995 et seq., and Fig. 464.) Any such lesion, whether of the sensory limb, nucleus, or motor limb, is capable of diminishing or destroying the reflexes. Such reflexes as the cutaneous, which are partly cortical, and which possess both lower and upper reflex arcs, require integrity of the lower reflex arc for the proper display of the reflex, because, according to the author's idea, the upper reflex arc has no functional independence, but merely incites the lower reflex arc to activity. So anatomic lesions of its nuclear arc cause a diminution or disappearance of that reflex. The disappearance of the tendon reflexes in tabes, and the disappearance of all the reflexes in peripheral neuritis and other peripheral paralyses, are examples in point. On the other hand, an accentuation of the reflexes results from an increase of irritability in the lower reflex arc, *e. g.*, in tetanus, in hysteric and neurasthenic states, and occasionally in the beginning stages of neuritis, especially while associated with hyperalgesia. The last may sometimes occasion difficulty in diagnosis.

The reflexes in cerebral hemiplegias and in transverse lesions of the cord have been so fully discussed in the preceding section (p. 992 et seq.) that only a few diagnostic points need be added. Cerebral hemiplegias can sometimes be diagnosed by the diminution of the cutaneous reflexes, and the alterations of the tendon reflexes (increase or decrease)

upon the paralyzed side, even during the "stroke," when the patient is still unconscious, and while, therefore, the motility cannot be directly tested. The abdominal reflexes, particularly the cremaster in men and the crural in women, are especially significant, unless these reflexes are absent upon both sides on account of inhibitory influences. In the latter event the criterion fails, and the condition is evidently more serious. Preservation of the cutaneous reflexes upon the paralyzed side should always be considered a relatively favorable prognostic sign, because it shows that the upper reflex arc through the cerebrum, whose motor limb is practically identical with the voluntary motor tract, has not been entirely destroyed. (See p. 992.)

In transverse lesions of the cord we generally find an accentuation of the reflexes whose nuclear arc lies below the injury. A decided increase of the cutaneous reflexes, *i. e.*, the appearance of pathologic skin reflexes, implies a serious lesion. On the other hand, a decided diminution of the reflexes originating beneath the lesion shows either that an inhibitory influence proceeds from the injury or that there exists a coincident involvement of the spinal segment situated below the lesion. Such an involvement may be the result of circulatory disturbance or of a distinct longitudinal lesion of the cord. Bastian, Kocher, and others consider that a traumatic lesion which causes a disappearance of the tendon reflexes of the lower part of the body is probably complete. The author's theory would attribute this to a decided inhibitory action in the lower segment, and perhaps also to a circulatory impairment from a lesion of the spinal arteries or other disturbances of circulation. At all events, later in the course of these cases, although the continuity of the cord is not reestablished, the tendon reflexes sometimes reappear. Our discussion upon the causes of the accentuation and variation of the cutaneous reflexes depending upon transverse lesions presents an important consideration for the operative treatment of spinal cord compression (spondylitis, etc.), *viz.*, the nearer the reflex approaches to the normal, the more liable the cord is to be merely compressed and otherwise intact. Again, the more profound and extensive the cross-lesion, the more pronounced will be the signs of what we have called reflex damming. In other words, decided accentuation or variation or loss of the reflexes argues in favor of a serious focal lesion and against simple compression. The preservation of certain reflexes is very important in cross-lesions, because it enables us to localize the level and the extent of the lesion (p. 1151 *et seq.*). The loss of them is, as we have seen, less serviceable for localizing diagnosis, because of so many indirect influences which can affect them.

In spastic paralyses it is very difficult to make any diagnostic use of certain reflexes. If the paralyzed muscles be rigidly contracted, neither cutaneous nor tendon reflexes can be sufficiently manifest in the very tense muscles. Sometimes this is especially noticeable in tetanus, where the permanent tension of the muscles prevents the ordinary reflexes, and yet the appearance of jerks at any irritation leads us to conclude that there is an accentuation of the reflexes.

The behavior of the vesical and rectal reflexes will be specially considered on p. 1162 *et seq.*

The influence of toxins on the reflexes has been recently studied. Schultz observed the Argyll-Robertson phenomenon in pneumonia, and a number of

writers¹ have frequently found the patellar reflex lost either on one or both sides in this disease. This illustrates the importance of the influence of toxins in the origin of tabes dorsalis.

QUALITATIVE ALTERATIONS OF THE REFLEXES; PATHOLOGIC REFLEXES

Many so-called pathologic reflexes should be regarded, from what was said upon p. 993, as deformations of the normal reflex, depending upon an encroachment of the reflex impulse upon pathways which become accessible to the impulse only because an obstruction is intercalated in the ordinary reflex tract in consequence of reflex damming. Frequently by this procedure the original reflex is only modified, so that, although disfigured, we can still recognize it. In other cases, however, reflexes occur, in quite an analogous way, entirely as pathologic phenomena. It is impossible to enumerate here all those which are observed in transverse lesions of the spinal cord; but there is a pathologic plantar reflex which is so frequently observed in such lesions that it deserves a brief notice. Stimulation of the sole of the foot, without producing plantar flexion of the toes and sometimes even without producing dorsal flexion of the ankle-joint, causes an exaggerated flexion of the thigh, often combined with external rotation. Not infrequently such movements are combined with reflex movements of quite distant muscle territories, *e. g.*, of the abdomen, of the opposite leg, and of the arms. This pathologic reflex can frequently be elicited by irritating other parts of the extremity, such as the thigh.

Babinski's phenomenon or the Babinski reflex (*phenomen des orteils*) consists of a dorsal flexion of the toes, but more especially of the great toe [and a simultaneous plantar flexion of the other toes.—Ed.], when the sole of the foot is irritated by pricking or stroking with a moderately sharp instrument. This reflex comes under the head of the pathologic plantar reflexes, and is sharply contrasted with the normal plantar flexion of all the toes on irritation of the sole of the foot. Babinski found that this reflex depended nearly always upon a lesion of the pyramidal tract. H. Schneider,² and many other writers [especially Walton and Paul, *Journal of Nervous and Mental Diseases*, 1903.—Ed.] have confirmed Babinski's original observation. Schneider explains this reflex as follows: In the ordinary reflex of the sole of the foot the, plantar flexion of all the toes depends upon a cortical component of the reflex; whereas the dorsal flexion depends upon a medullary component of the reflex. With a lesion of the pyramidal tract, the reflex for the plantar flexion is interrupted, but not that for the dorsal flexion. Babinski's reflex may also be produced by an increase of the medullary component of the reflex, just as well as by a lesion of the pyramidal tract; therefore, its demonstration does not prove absolutely a lesion of the pyramidal tract. It seems to the author, however, that the hypothesis of deformations of the reflexes by damming, which he has advanced, will explain the transformation of the usual plantar reflex into Babinski's reflex quite as well as Schneider's hypothesis. Babinski's reflex may be obtained more readily by stroking the outer than the inner plantar margin. In fact, several cases have been reported in which a Babinski reflex could be elicited from the outer margin, and a plantar flexion of the toes from the inner margin, of the sole of the foot. A plantar reflex of the Babinski type may be produced if, in a nuclear lesion of the lumbar cord or in a peripheral palsy of the lower extremities, the flexors of the toes are paralyzed, either alone or in a greater degree than the extensors. In this case the reflex impulse in the extensors preponderates. Physiologically, the Babinski reflex appears in sleep, at the commencement of narcosis, and during the first year of infancy.

Oppenheim's dorsotibial phenomenon is analogous to Babinski's sign; and, like the latter, is capable of different explanations in isolated cases. It consists of a dorsal flexion of the foot and toes when the inner surface of the leg is stroked, whereas under ordinary circumstances either no reflex at all or a plantar flexion of the toes and foot would result.

K. Mendel³ has described an additional pathologic "dorsum foot-reflex," which was also described by von Bechterew, and is sometimes called Bechterew's "flexor reflex." According to Mendel, if one tap the dorsum of the foot of healthy indi-

¹ Marinian, *Rivista Clinica*, Bologna, 1884; Longard, *Zeit. f. Nervenheilk.*, 1891; Luethje, v., *Munch. med. Woch.*, 1902, No. 32; Burnes, *Birmingham Med. Review*, April, 1907; and Wiens, *Zeit. f. klin. Med.*, 1908, vol. lxxv, p. 53.

³ *Neurol. Centralbl.*, 1904, p. 5.

viduals or those suffering from functional diseases, there will either be no reflex at all or a dorsal flexion of the second to the fifth toes inclusive. In certain organic diseases, however, there is a plantar flexion. According to Mendel, this anomaly is usually but not always combined with Babinski's sign. Very recently L. Jacobsohn¹ has described a reflex of the hand analogous to the Babinski reflex, which, according to him, is constantly found in cases of cerebral spastic paralysis of the upper extremities. He describes the reflex as follows: The patient rests his forearm upon the examiner's hand, with the thumb directed upward, the fingers slightly extended. A blow is then struck with a percussion hammer upon the lower end of the radius on the extensor side. If a flexion of the fingers, especially of the distal ends, results, cerebral spastic paralysis is suggested. Normally, the fingers remain extended.

Fig. 384.—Plantar reflex: 1. Foot at rest; 2. plantar flexion (normal); 3. foot at rest; 4. dorsal flexion of great toe (Babinski's reflex).

About the same time von Bechterew also described this reflex and established its analogy to the Babinski reflex. This, however, is obviously a periosteal reflex, while the Babinski reflex is purely cutaneous. Furthermore (see the previous discussion of the Mechanism of Reflexes), our conception of the cutaneous reflex differs in principle from the periosteal or tendon reflexes. As a matter of fact, probably every attentive observer has seen this reflex appear in the contracted upper extremities of hemiplegics, and has considered it in the light of a simple increase of tendon and periosteal reflexes. The deformation in the Babinski reflex, on the other hand, is a normal cutaneous reflex appearing in another form. This does not, at all events, alter the fact that Jacobsohn's reflex as well as the Babinski reflex and, in fact, all exaggerated periosteal and tendon reflexes are important indications

¹ Deut. med. Woch., 1908, No. 46.

of lesion of the central neuron. They have always been considered as such, even without the apparently not quite justifiable analogy to the Babinski reflex.

In transverse lesions of the spinal cord the frequent occurrence of ejaculation and erection reflexes, excited by light stroking of the genital or anal region, of the perineum or of the thigh, should be mentioned, as well as bladder and rectal emptying from touching a bed-sore, etc. The testicle reflex described by Kocher in spinal-cord affections consists in a lateral bending of the spinal cord toward the irritated side when the testicle is firmly pinched. The author can confirm the appearance of this reflex in transverse lesions of the spinal cord. Whether it should be considered as pathologic is not easy to determine, because the attempt in healthy individuals, *i. e.*, those with normal sensibility, is very painful and possibly injurious.

Other abnormal reflexes may occur both from cutaneous and from tendon reflexes without assuming damming, but simply from increase of reflex irritability. In this way the impulse can no longer be limited within the stimulated territory, but diffuses itself, according to Pflüger's laws, in horizontal and then in longitudinal directions (p. 988). These phenomena really belong to the section upon Quantitative Alterations.

V. EXAMINATION FOR TROPHIC DISTURBANCES

1. TROPHIC DISTURBANCES OF THE MUSCLES

(a) Increase in Volume of the Muscles; Hypertrophy and Pseudohypertrophy

True hypertrophy of the muscles, *i. e.*, an enlargement with increased strength, is a very rare pathologic condition. It occurs, however, in Thomsen's disease and in true congenital muscular hypertrophies. The latter are rarely observed, and still very imperfectly understood. In most cases the pathologic increase in volume of the muscles is not an actual hypertrophy, but a pseudohypertrophy, since it depends not upon an increase of the contracting muscular fiber, but upon a growth of interstitial connective tissue and of fat. The variety of muscular atrophy known as pseudohypertrophic progressive muscular atrophy furnishes the best example of this pseudohypertrophy. Now and then other myopathic forms of chronic progressive muscular atrophy show pseudohypertrophy in some of the affected muscles.

(b) Decrease in Volume of the Muscles; Muscular Atrophy

Atrophy of Disuse; Simple Non-degenerative Atrophy.—This means a diminution of the contractile substance which goes on in every muscle that is not used. An absolute increase of interstitial connective tissue does not accompany it, and for this reason this type is designated as a non-degenerative atrophy. Paralysis, mechanical fixation of an extremity, or a restrained position of the latter from some painful affection may gradually produce an atrophy of disuse. This atrophy becomes pronounced only when the immobility is quite absolute. The differentiation of atrophy of disuse from degenerative atrophy is easy without the aid of electric examination, because the volume of that part of the body which shows the atrophy and which is no longer moved is diminished *in toto*; while in degenerative atrophy frequently individual muscles or groups are spared or are predominantly involved in the atrophy.

The above rule, that an atrophy of disuse which depends upon partial inaction of the muscles never attains a very high degree, does not hold good in the case of paralysis appearing in a growing individual. The physiologic growth then seems to be decidedly inhibited by the

inaction, even if very limited, *e. g.*, we frequently observe very marked atrophies in the cerebral paralysis of children, and we can usually definitely determine that these are not degenerative, by means of the anatomic localization of the primary lesion and by electric and anatomic examination of the muscles. It should, nevertheless, be remembered that some of the marked atrophies consequent upon cerebral paralysis in children are possibly also of a degenerative nature, and are brought about in the manner indicated in foot-note 2, on p. 1001.

Degenerative Atrophy.—Degenerative muscular atrophies are distinguished from atrophies of disuse by the presence, in the affected muscles, of a pathologic proliferation of interstitial connective tissue, which develops as well in those idiopathic muscular atrophies called progressive as in the so-called atrophic paralyses.

Progressive Muscular Atrophies.—These include *myopathic*, *neuritic*, and *spinal* (better nuclear) forms, depending upon whether the muscles are primarily diseased or whether they atrophy secondarily to a chronic neuritis or to a chronic degeneration of the large ganglion-cells or nuclei of the spinal cord (or the nuclei of the cranial nerves). In all three forms certain muscles and muscle groups gradually disappear. The atrophy affects the muscles individually and increases gradually, but an entire extremity does not show diffuse atrophy until an advanced stage of the process has been reached. The muscular power diminishes in proportion to the disappearance of the muscles. This is in contrast with the *atrophic paralyses*, in which the paralysis appears before the atrophy. The question whether a muscular atrophy is myopathic, neuritic, or nuclear is made easier to answer by knowing that each of these forms has a characteristic way of spreading.

(A) Under the *myopathic* form, lately designated by the term *dystrophy*, several groups have been described. Three of the most important are:

1. Erb's juvenile muscular atrophy (progressive muscular dystrophy), which begins in the shoulder-girdle. There are different types of this group.

2. Leyden-Moebius' juvenile form; this begins in the lower extremities. Pseudohypertrophy is closely related to this form. (See p. 999.)

3. Duchenne's infantile variety; this begins in the face.

(B) *Nuclear (spinal) muscular atrophy* begins in the small muscles of the hand and involves early the bulbar nuclei, *i. e.*, produces the picture of bulbar paralysis (better, bulbar atrophy).

(C) The *neuritic* or *neural type of progressive muscular atrophy* is still the least understood. It begins most frequently in the lower extremities, in the domain of the peroneal nerve (peroneal type), and causes a pes varus or equinovarus. Ordinarily, disturbances of sensibility are associated with this form.

Other methods of differentiating these three forms are as follows: *Fibrillary twitching* (p. 956) and *reaction of degeneration* (p. 1023) are demonstrable in the spinal and neuritic forms, but rarely in the myopathic. Disturbance of sensibility, even though very slight, points to the neuritic type. Myopathic muscular atrophy is, as a rule, hereditary, or familial (less characteristic in Erb's type), and affects almost exclusively young individuals. The same is true for some of the neuritic cases; but the spinal form is almost entirely confined to older people without neuropathic heritage.

The examination of the nervous system by means of the newer methods based upon more minute histology of the ganglion-cells will probably determine that the boundaries of the individual forms are in no way so sharply defined as we have thus far assumed. In this regard the entire subject of muscular atrophies, especially neuropathology, needs anatomic revision.

Secondary Degenerative Muscular Atrophies After So-called Atrophic Paralysis.—Paralysis are described as atrophic when the cause of the paralysis deprives the muscles not only of the impulse of the will, but also of the trophic influence of the cells of the nerve nuclei, *i. e.*, the cells of the cord situated in the gray anterior horns.¹

To avoid confusion with the *simple atrophies of disuse* (p. 999 et seq.), we should remember that the *secondary degenerative atrophies* depend entirely upon a lesion located either in the nucleus or peripherally to it (nuclear and peripheral paralysis).² They may be included in the class of paralysis from lesion of the peripheral neuron.

These atrophies ordinarily follow the onset of the paralysis quite rapidly, *i. e.*, within a few weeks. They affect individual muscles very differently, depending upon the degree of the paralysis, and ordinarily attain a very high grade, even to complete disappearance of individual muscles. They present the reaction of degeneration often even before the diminution of volume has become evident. (See p. 1023.) They are also frequently associated with fibrillary twitchings (p. 956). Such atrophies are always an indication of severe paralysis and require a long time for recovery—many months—even in favorable cases. The prognosis is not always absolutely unfavorable in lesions located peripherally to the nuclei, since the regenerative power of peripheral nerves is exceedingly good. The prognosis of the degenerative atrophies which arise from lesions of the nuclei themselves is, on the other hand, absolutely hopeless, because in such cases regeneration does not occur (acute, subacute, and chronic poliomyelitis).

The lack of well-marked appearances of regeneration in these cases, in fact, in any severe focal lesion of the central nervous system, is probably not due to the fact that central nervous tissue possesses less power of regeneration than peripheral. On the contrary, the presence of isolated degenerated fibers in the normal central nervous system, recently demonstrated by Edinger, would indicate that the physiologic wear and tear of the nervous system must be associated with a physiologic regeneration, since otherwise progressive disturbances would result. In fact, even in severe pathologic focal lesions certain anatomic indications of regeneration have been found. That such attempts at regeneration are abortive in severe focal lesions, leading to destruction of tissue, lies in the fact that in them newly formed nerve-fibers find neither a suitable soil nor the proper functional connection to the closely related elements from which they are separated by long distances. If, on the other hand, there be not a severe destructive process, but rather an individual disease of single elements, as, for instance, in the so-called system diseases, the possibility for regeneration in the central nervous system cannot be excluded. Thus the subsidence of paralytic phenomena in acute anterior poliomyelitis is to be attributed to regeneration of those parts in which gross destruction has not taken place; whereas those parts which are involved in the actual inflammatory focus naturally cannot regenerate because of the reasons mentioned above.

¹ The ordinary assumption that these nuclear cells preside over this trophic influence is scarcely correct. However, as centers of spinal reflexes, *i. e.*, of the tendon reflexes, they probably preserve the muscle tonus and prevent a complete muscular inactivity if the muscles are paralyzed above the nuclei.

² In reference to the rare cases of degenerative muscular atrophy following lesions of the central motor neuron, and its possible explanation in the extension of the descending degeneration to the peripheral neuron, the reader is referred to the article of Steinert ("Cerebrale Muskelatrophie," *Deut. Zeit. f. Nervenheilk.*, 1903, vol. xxiv, parts 1 and 2).

If a degenerative paralysis does recover, the volume of the muscle gradually returns, following the reappearance of motility and improvement in the electric irritability.

2. TROPHIC DISTURBANCES OF THE SKIN

Ordinary Decubitus.—This occurs in all sorts of severe diseases, and especially in transverse lesions of the spinal cord. It consists of necrotic processes in the skin and subcutaneous tissues of those parts which endure the principal weight of the body while lying in bed—the sacrum, the trochanters, and the heels. In mild cases there is simply an exposure of the corium from destruction of the epidermis; in more severe cases, a deep necrotic destruction of the tissues, even down to the bone. The phenomenon is practically a pressure necrosis. Since decu-

Fig. 385.—Perforating ulcer in tabes. X-ray plate showed involvement of the bone (Dr. J. J. Putnam, Massachusetts General Hospital).

bitus is never found in health, we are naturally inclined to consider it due, in a certain sense, to some trophic disturbance, not to an actual affection of trophic centers or trophic nerves, because it is so common in diseases which have no nervous involvement, but rather to the generally depressed nutrition, in which the skin shares. Decubitus is frequent in transverse lesions of the spinal cord, because the enforced quiet is often responsible for impoverished nutrition, the difficulty in moving the patient favors more constant pressure upon the dependent places, and, even if movement be possible, the impaired sensibility prevents recognition of inequalities, such as folds in the bed-clothes, which a healthy person would instantly avoid. Disturbance in the functions of the bladder and rectum, so frequent in these conditions, often keeps the sacral region unclean, and so gives rise to infection. The trophic influence mentioned on p. 1062 (trigeminus), which unques-

tionably passes among the sensory fibers, must also be considered as affecting the sensory conduction of the peripheral neurons.

Acute Unilateral Decubitus.—The trophic influence of the nervous system seems to be more striking in acute unilateral decubitus. This consists of a rapidly increasing necrosis of the skin over the sacrum, which is observed upon the side of motor involvement in severe cerebral hemiplegias, and upon the side of the sensory paralysis in spinal hemiplegias. The unilateral character of the phenomenon shows the influence of the nervous system, but at the same time actual trophic elements of the nervous system are not necessarily responsible. It is quite possible that in cerebral hemiplegias the essential fault is dis-

Fig. 386.—Saber shin (Dr. Joseph Collins, New York City Hospital).

turbance of sensation, which robs the patient of the instinctive protection against considerable pressure upon the anesthetic side. Lesions of the trophic influence of the sensory cutaneous nerves (see p. 1062, trigeminus) must also be considered in sensory disturbances of the peripheral neurons. Acute unilateral decubitus is generally an unfavorable prognostic sign, but merely because it arises only in very marked paralysis; for recovery both as regards life or even usefulness is by no means excluded by the presence of this condition.

Changes in the Skin Over Paralyzed Parts.—The skin over peripherally paralyzed parts, more noticeably the hand, frequently presents a characteristic thin, atrophied, shining appearance—the so-

called *glossy skin*. Conversely, an increase in the subcutaneous fat frequently masks the muscular atrophy, especially in the cerebral, but also in the spinal, paralyses of children.

Other Trophic Changes of the Skin.—It is impossible to discuss here all the changes of the skin which we meet with in diseases of the nervous system. We shall merely mention the presence of pigmentation, of abnormalities in the formation of the epidermis and in the growth of the hair, of deformities of the nails (onychogryphosis), of the loss of the nails (alopecia unguium), of herpes zoster, of symmetric gangrene (maladie de Raynaud, syringomyelia), of panaritium (Morvan's disease; syringomyelia), of Dupuytren's contracture, and of perforating ulcer of the foot. (See Fig. 385.) All these occur predominantly with disease (functional or anatomic) of the peripheral neurons, and for their description we must refer to special pathology.

3. TROPHIC DISTURBANCES OF THE BONES AND JOINTS

In all paralyses occurring in early youth, whether peripheral or central (cerebral and spinal paralyses of children), the growth of the bone

Fig. 387.—Tabetic arthropathy of left ankle (New York City Hospital).

is impeded; on account of such an inhibition of growth and the associated degenerative atrophy of disuse, the paralyzed extremity is much smaller.

An abnormal *fragility* of the bones, which is responsible for the so-called spontaneous fractures, occurs in tabes dorsalis, syringomyelia [and

in elderly individuals who have been confined to bed for a long period of time.—Ed.].

Joint affections are observed in the most diverse diseases of the nervous system. They depend frequently upon purely mechanical causes (stretching a joint by the suspended paralyzed extremity or contractures), yet sometimes they are probably due to actual trophic disturbances. Even here this expression does not mean that the disturbances depend wholly upon a lesion of the nervous system, nor can we consider that a nervous apparatus whose only function is trophic has been affected. (See p. 1062, Trigeminal Peripheral Sensory Fibers.)

Fig. 388.—Tabetic arthropathy of the knee (Dr. Joseph Collins, New York City Hospital).

Perhaps the joint affections which occur in tabes, and which we designate as *tabetic arthropathy*, should be included under such trophic disturbances. (See Figs. 387 and 388.) They are ordinarily characterized by their onset, which is abrupt and painless, by the presence of a considerable fluid, effusion by loosening of the joint, and by a growth of bone and cartilage, leading to deformity of the joint. The knee-joint is most commonly affected, and soon becomes an actual flail-joint. The ankle-joints are also subject to tabetic arthropathy, although not nearly so extensively.

These specific peculiarities of tabetic arthropathies argue against the purely mechanical explanation which has been so frequently assumed, viz., that on account

of the ataxia the joint suffers repeated injuries from which the patient, because of the joint anesthesia, is unable to protect himself. Other reasons for assuming a trophic influence are the characteristic wearing away of the bones (eburnation fracture of the bones in the direct neighborhood of the diseased joint) and their insensibility to tuning-fork vibrations (p. 974). Even here the author does not consider it necessary to assume the existence of special trophic nerves to explain the joint affections and the bone brittleness of tabes, because a sufficient reason for disturbance in growth seems to him to be furnished by the anesthesia of the bones and joint ends, as well as by the occasional involvement of the vasomotor nerves.

J. Wolf's signal work on the "Transformation of Bones" proves incontrovertibly that the structure of the spongiosum is influenced in the most delicate way by the requirements of its work, which, in view of the already proved trophic significance of sensation, can be accomplished so completely either by means of the vasomotor reflexes or because trophic influences pass centrifugally among the sensory fibers through the influence of bony sensibility alone. (See p. 1062, *Trigeminus*.) It may be considered established beyond question, by physiologic experiments on the variations of the negative current, that sensory fibers also conduct impulses centrifugally and motor fibers conduct centripetally as well.

Acromegaly, a peculiar disease characterized by hypertrophy of the bones of the hands, of the feet, of the nose, and of the lower jaw,

Fig. 389.—Myxedema (Dr. Townsend, Massachusetts General Hospital).

possibly depends upon some trophic disorder of the nervous system. The enlargement is often very marked. The reader is referred to

works upon special pathology for a discussion of its origin and its possible dependence upon an altered internal secretion of the hypophysis cerebri without any other connection with the nervous system.

VI. EXAMINATION OF VASOMOTOR DISTURBANCES

We know so little about the vasomotor relations in nervous disease that it is scarcely worth while to enter upon a general discussion. The author will limit himself to a few remarks, at the same time referring to the section upon the Examination of the Skin (p. 39 et seq.), and to what was said there of local cyanosis.

Vasomotor differences between the paralyzed and the normal half of the body are sometimes found in *cerebral hemiplegias*, especially if the lesion causing the hemiplegia be situated in the pons, peduncles of the brain, or the internal capsule. In the beginning the paralyzed extremities ordinarily appear warmer and redder; later, colder than normal, and cyanotic. What causes these peculiarities is not yet fully understood. Since the cerebrum, as shown by the action of psychic irritation, possesses an influence upon the vasomotors, the initial heat and redness can be explained by assuming a paralysis of the vasomotor tracts of the brain. The vicarious action of the vasomotor centers of the spinal cord, however, quickly changes the condition. The coolness and cyanosis of the skin of the paralyzed side, which appear later and which ordinarily continue as long as the paralysis lasts, probably have nothing to do with the vasomotor action (though this is opposed to the ordinary supposition), but depend upon a stagnation of the venous blood, caused by the immobility of the extremities. Muscular action in movement of an extremity, as is well known, has great influence in propelling the venous blood forward. Perhaps the diminished heat-production in the paralyzed muscles is another factor.

In *transverse lesions* of the spinal cord, the higher the lesion, the more profound is the vasomotor paralysis of the lower half of the body. In lesions of the oblongata, the paralysis of the main vasomotor center and the dilatation of the vessels may lead to a fatal sinking of blood-pressure, accompanied by marked cyanosis and coolness of the peripheral parts. In transverse lesions situated below the oblongata, the paralysis of the vasomotors (vasoconstrictors) affects the territory innervated by that part of the spinal cord situated below the lesion, because the vasoconstrictor impulses of the oblongata, except those supplying the head, run downward through the spinal cord and leave the cord along with the motor nerves for the same territory, to merge into the sympathetic system. The territory showing motor paralysis then also shows vasomotor paralysis. This is sometimes evident by increased temperature and redness of the paralyzed limb. Yet this paralysis is ordinarily slight and often transitory, because the vasomotor apparatus situated beneath the lesion, as well as the sympathetic fibers of the spinal cord arising above the lesion, are able to functionate vicariously for the nerves which have been cut off. Later, the paralyzed parts frequently become cool and cyanotic on account of the immobility, as in cerebral hemiplegia. *Priapism*, so frequently observed in transverse lesions of the spinal cord, probably depends upon a vasomotor paralysis. The vasoconstrictor fibers of the face probably first issue from the spinal cord in the region of the upper dorsal cord (according to animal experiments on the spinal cord, see p. 1157, Dastre and Morat). Therefore, they may be affected in all lesions of the spinal cord situated above the sixth dorsal nerves. As yet we know nothing definite about the behavior of vasodilator nerves in lesions of the brain and spinal cord.

Tache cérébrale, Trousseau's spots, dermographism, are the different names applied to a cutaneous vasomotor phenomenon which probably depends upon changes in irritability of the vasomotor nerves. It consists of a deep-red color of the skin, often accompanied by the formation of a wheal wherever the skin is irritated, *e. g.*, by light scratching with the finger or the head of a pin. It occurs in purely functional diseases, sometimes in brain diseases (especially meningitis), and not rarely in spinal-cord diseases.

For the description of the peculiar reddening of the skin in *erythromelalgia* and of the mixture of bright red, pallid, or cyanotic discoloration in *Raynaud's disease* we must refer to special pathology.

VII. EXAMINATION OF DISTURBANCES OF SECRETION

Abnormalities of sweat secretion are common, but as yet we cannot accord them much diagnostic significance. Hemihyperhidrosis and hemianhidrosis, *i. e.*, unilateral increase or absence of sweat production, often occur physiologically in otherwise healthy persons. In such a case a suspicion of a disease of the sympathetic system is natural. We also observe hemihyperhidrosis in syringomyelia. In hemiplegias of cerebral origin, sweating of the affected side is sometimes more, sometimes less, marked than upon the healthy side; frequently, however, it is entirely normal. A decided tendency to increased perspiration is often noted in extremities which are affected with an *acute polyneuritis*, even when there is no fever. This is peculiar and of some diagnostic importance.

We know so little about the alteration of urinary secretion in diseases of the nervous system that it is impossible to draw diagnostic conclusions. A pale, abundant urine of low specific gravity (*urina spastica*) generally follows attacks of *epilepsy* and *hysteria*. *Transitory glycosuria*, or even *diabetes mellitus* ending in death, often accompanies diseases of the brain, particularly when situated in the posterior cerebral fossa. *Diabetes insipidus* has a predilection for neuropathic individuals, especially neurasthenics.

Since anatomists have succeeded in demonstrating nerve-endings in the epithelium of the renal parenchyma, cells which can obviously have a secretory significance only, the relationship of this peculiar disease to the nervous system has become much clearer. (See p. 55.) [An enormous output of urine is sometimes associated with tumors of the hypophysis.—Ed.]

Pathologic variations of the *salivary secretion* are mentioned in the section upon Examination of the Facial Nerve.

VIII. EDEMA IN NERVOUS DISEASES

It is not certain that acute idiopathic edema really depends upon the nervous system, but certainly the name, "angioneurotic" edema (see p. 55), rather prejudices one in favor of such an origin. The edemas which complicate actual nervous diseases are: (a) The so-called "*blue edema*" of hysteria. This is discussed under the heading of Angioneurotic Edema (p. 55), and its occurrence was utilized as an argument for assuming that hysteric symptoms are frequently to be attributed to vasomotor disturbances. (b) Whether the *edema of the paralyzed members of all kinds of paralysis* is due to vasomotor paresis must be determined in each case; but the immobility and lack of muscular activity leading to venous stasis (as explained upon p. 1007) are generally a sufficient explanation. (c) The *edema of the paralyzed members in polyneuritis*. A vasomotor origin in such cases is especially plausible, because if the peripheral vasomotor fibers be involved, the vasomotor disturbance would be exceptionally pronounced, since, as contrasted with cerebral and spinal paralysis, the vicarious action of the auxiliary vasomotor centers, with the exception of those situated on the vessels themselves, is cut off. Still, with the edema of neuritis, we should also consider the possibility of an inflammatory origin.

IX. METHOD OF TESTING THE MECHANICAL IRRITABILITY OF NERVES AND MUSCLES

1. MECHANICAL IRRITABILITY OF MOTOR NERVES

Contraction of a muscle may sometimes be produced by striking the nerve supplying it with a percussion hammer. This occurs in health under the appropriate conditions, *e. g.*, when the nerve runs

superficially upon some firm underlying tissue. This mechanical irritability is increased in *tetany*, especially in the facial nerve (facial phenomenon, Chvostek's phenomenon), and more rarely in *writer's cramp*.

2. MECHANICAL IRRITABILITY OF MUSCLES, IDIOMUSCULAR MECHANICAL IRRITABILITY (Schiff)

Only vigorous percussion will stimulate muscles in health. Such a stimulation causes a sudden, quick contraction of the bundles of fibers which lie in the long axis of the muscles near the point struck. At the same time a smooth local prominence is produced at the spot tapped, or in the long axis of the muscle at a greater or less distance. After a lapse of some seconds this prominence very gradually disappears or first merges into a series of waves running along in the direction of the fibers.

In most *cachectic conditions* (tuberculosis, carcinoma, etc.) the idiomuscular irritability is apt to be increased and the muscular prominence quite pronounced.

The mechanical irritability is also increased wherever muscle exhibits reaction of degeneration with increased galvanic irritability. (See p. 1025.) The longitudinal wave-like contractions are here exceptionally slight, and much slower than the normal. This phenomenon is called mechanical reaction of degeneration.

Curschmann's work¹ should be consulted in regard to idiomuscular mechanical hyperexcitability.

X. METHOD OF TESTING ELECTRIC IRRITABILITY²

1. GENERAL DISCUSSION

Electric examination of sensory nerves, including the nerves of special sense, has not yet developed anything of practical value except the method described on p. 976. The following description will therefore be limited to the electric examination of motor nerves and muscles.

For this purpose a faradic (induced, interrupted) or a galvanic (constant) current is employed almost exclusively. One of the many modifications of the Du Bois-Réymond sliding apparatus with one or two zinc-carbon cells will furnish the faradic, while for the constant current the stationary Leclanché batteries are most useful. These latter are expensive and cannot be transported, so that a portable battery with sulphuric-acid-zinc-carbon elements [or one of the standard dry-cell batteries.—Ed.] is better adapted for the practitioner's needs.

Owing to the progress of modern electric technic and the more general use of the electric current, the galvanic batteries for medical purposes have been replaced by apparatus which transforms the ordinary current for medical use. It cannot

¹ Deut. Zeit. f. Nervenheilk., 1905, vol. xxviii, Nos. 5 and 6, p. 361.

² Testing the electric resistance of the body, which is essentially dependent upon the condition of the skin, and the standardization of which can be reckoned in milliamperes, is no longer of importance in testing electric excitability, because its influence can be reckoned by reading the current strength. (See p. 55, Examination of the Skin.) If the electric findings be reckoned, not by the strength of the current, but by the voltage or by the number of elements, the cutaneous resistance will naturally affect the results. The amount of the resistance can be obtained, according to Ohm's law, by reading the strength of the current, and its influence computed accordingly.

be said, however, that these installations have made electrodiagnosis or electrotherapy more exact. The difficulty lies in the fact that the so-called constant currents obtained from these apparatus cannot always be considered as a single galvanic current, although this is claimed for them. This is true both for the constant current taken directly from the street wire and for the current of a voltage suitable for medical purposes transformed from the alternating current. Many of these so-called constant currents are more or less pulsating, according to the character of the dynamo. The so-called constant currents, which do not flow quite evenly, are not proved, according to the author, equal to the pure galvanic current in a physiologic sense. Many firms utterly disregard this question, and most physicians accept as galvanic the constant currents offered as such without any exact proof of their constancy. It is clear that the existence and number of pulsations in a current can cause essential differences in the effect of the stimulation. The practitioner, however, cannot judge of the more delicate qualifications of such a constant current, and the author considers, speaking generally, that only such central stations are of value for electromedical purposes where the current is taken not directly from the generator, but from large interposed storage batteries. The equalizing effect of interposing the large electric reservoirs of a storage battery will eliminate the physiologic effect of the dynamo pulsation. The author is very skeptical of the results obtained recently with cabinets whenever the current is not in constant connection with a storage battery. To a certain extent the same objections apply to the use of faradic appliances which derive their current from a central station. In this case, however, it has less significance, because the results of faradic tests are only of value for each apparatus at the time of use and absolute standards are in any case excluded.

To maintain, therefore, the reputation for accuracy which electrodiagnosis owes to the *battery current*, it would be highly advisable to use the current known, technically, as a constant current, to store local storage batteries whenever the central station is not so supplied, in place of the older cell batteries. To the convenience of a stationary storage battery as against the ordinary galvanic battery should be added the absolute certainty of having an actual galvanic current, *i. e.*, a perfectly constant and non-pulsating current.

The diagnostic application of the so-called sinusoidal current has been studied too little from a scientific standpoint to be discussed here.

For stimulation we employ flat electrodes or those terminating in a bulb. They are covered with chamois leather, and before being used should be moistened with warm water. If salt be added to the water, the current strength is increased, but the electrodes soon become tarnished and spoiled. Different sizes of button-shape and flat electrodes are required, and some of the former should be made with a contact contrivance for opening and closing the current.

For an accurate electric examination we need an appliance to measure the strength of the galvanic current. Until recently this purpose has been served by a galvanometer divided, according to the absolute strength of current, into milliamperes. The apparatus of Gaiffe (Paris), Edelman (Munich) [or Edison (New York).—Ed.] can be recommended. The galvanometer is an essential for electrotherapeutic purposes; but the voltmeter offers many advantages for electrodiagnosis. (See later, p. 1015 et seq.)

Medical batteries are supplied with a commutator, or current changer, for quickly changing the poles, and with a contrivance for connecting or disconnecting the individual cells in order to increase or decrease quickly the strength of the current. Finer gradations are obtained by inserting a fluid rheostat into the main circuit. Although quite practical with the ordinary galvanometer, a rheostat in the main circuit cannot be used with the voltmeter, *i. e.*, a galvanometer with a very strong resistance in the lateral circuit, and so is not practicable for diagnostic purposes. If we use the voltmeter, we must employ either a rheostat in lateral circuit or, still better, the "Gaiffe reducteur

de potentiel." If the street current be used, the reduction occurs also by means of the potential reducer or the volt regulator.

The faradic current is reduced by approximating the secondary coil to the primary. Faradic stimulation means stimulation with a free swinging interrupter; that is, with a rapidly alternating current (tetanizing stimulation). The apparatus can also be used to produce single induction shocks, by fastening the Neef hammer and opening and closing the primary current manually. This is of very great practical advantage because, in peripheral palsies, especially those with greatly diminished excitability, this method produces much less pain than the tetanizing form. Besides, degenerating muscles react longer to single interruptions than to the tetanizing alternations, a very important therapeutic point in the treatment of paralyses.

The polar method of electric stimulation is nowadays ordinarily employed for electric examination. One pole is placed upon the spot to be stimulated, the other upon an indifferent spot, as far distant as possible, *e. g.*, upon the abdomen or the breast. The examination is thus essentially simplified by disregarding the direction of the stream. For all practical purposes both poles of the faradic current may be said to act alike, although not with equal strength. With the galvanic current, on the other hand, there is a fundamental difference between the two poles. This difference is apparent in the so-called laws of contraction of motor nerves and muscles. The cathode of the opening induction current acts most powerfully; therefore it is agreed to employ this for faradic stimulation. On the other hand, in every case where we use the galvanic stream, we must test cathode and anode stimulation separately and compare the results.

The active electrode should not be too large if the object be to stimulate isolated nerves or muscles. Too small electrodes are impracticable, because with them the intensity of the current is so great that the pain of the examination is materially increased. For most purposes a button-shaped electrode of 1 to 2 cm. diameter answers the purpose. If we wish to compare the results of different electrodiagnostic examinations, uniform electrodes should be used, since the stimulation effect depends not only upon the strength, but also upon the intensity of the current. (See p. 1019.) Erb and Stintzing recommend so-called normal electrodes for all electric examinations. Erb's normal electrode is 10 sq. cm. in size (a circular surface of 3.6 cm. diameter). Stintzing's electrode, which is serviceable for stimulating small muscles (*e. g.*, of the hand), has a circular surface of 3 sq. cm. (1.8–2 cm. diameter). The indifferent electrode should be as large as possible, in order to decrease the intensity of the current through it, even when a strong current is employed, and so to lessen the pain caused by the passage of the current. The pain is due essentially to electrolyzing the skin.

There are some exceptions to the rule given above, that the indifferent, large electrode should be applied as far as possible from the point to be stimulated. These exceptions occur frequently enough to merit mention, *e. g.*, when employing strong currents in diminished irritability, if we should apply the indifferent electrode to the abdomen and then attempt to stimulate the small muscles of the hand, the effect would be very confusing. The current passing through the nerves and muscles of the arm would produce contraction of the muscles not only of the hand, but also of the arm; the entire arm would naturally be jerked

about, and so confuse us. In such a case it would be better to apply the indifferent electrode to the other surface of the same hand. The employment of the largest possible indifferent electrode establishes a great difference in current intensity between the two electrodes, so that an almost exclusive, and practically a polar, action results at the differentiating electrode. Such devices should be made use of upon other parts of the body.

A complete electric examination, evidently, must include testing each muscle and nerve. It consumes a great deal of time, because control tests must be made in order to verify results. In fact, the electric examination of an extensive paralysis requires more time, skill, and patience than any other kind of examination, if it be accurate and thorough, and leads to many serious errors if it be carried out hastily or carelessly. An accurate testing of one muscle is of more service than the careless examination of all the paralyzed muscles. *Multum* is better than *multa*; quality, than quantity. A complete examination of all the muscles implicated in a paralysis is impracticable for a busy practitioner, especially if, in the interest of prognosis, continued changes in the reaction during the course of the disease are to be followed. Testing some few muscles and nerves is, fortunately, sufficient for diagnostic purposes.

A complete electric examination of a nerve muscle should include testing of both muscle and nerve by the galvanic as well as by the faradic current. A nerve generally reacts the same to galvanism as to faradism, so that, if anything has to be slighted, it is advisable to omit the galvanic test. Still, the latter has here, as elsewhere, a distinct advantage over faradism, because with it the amount of stimulation can be measured.

There are certain places scattered over the surface of the body which, when stimulated by a small electrode, evoke the best response from one definite nerve or muscle. These are the so-called "motor points" determined by Duchenne, Erb, von Ziemssen, and others, and make possible the individual stimulation of single motor nerves and muscles. They are represented in the accompanying figures (Figs. 390 to 394). Their location has been confirmed by the author's own examinations. Most motor points for nerves are situated where the nerve lies superficially and at some distance from other nerves. The motor point of a muscle is usually at the point where the motor branch of the nerve enters the muscle belly. In point of fact, the nerve is here stimulated also; therefore, when endeavoring to obtain a pure muscular reaction, it is a good plan to keep as far as possible from the motor points, unless the nerve irritability be lost. In this way stimulation will produce local contractions only in the individual bundles which are stimulated.

In all electric tests it is essential to determine three factors: First, whether both the motor nerve and the muscle still react to the faradic and to the galvanic current; secondly, whether the reaction to either current be quantitatively altered, *i. e.*, whether it be increased or, as most frequently happens, diminished; and, finally, whether any qualitative alteration in irritability can be demonstrated, *i. e.*, any deviation from the ordinary type of contraction. With the galvanic current the effect of each pole must be noted.

The "dosage," *i. e.*, the strength of current employed, must always be estimated in examining for quantitative changes.

This has been done heretofore in using the galvanic current by reading the strength of the current. The latter may change so very rapidly

that in closure contraction it must be read immediately. In examination of the opening contraction, it is read just before the contraction

begins. Before taking the reading, the current should be allowed to flow through the body and the galvanometer until the needle of the

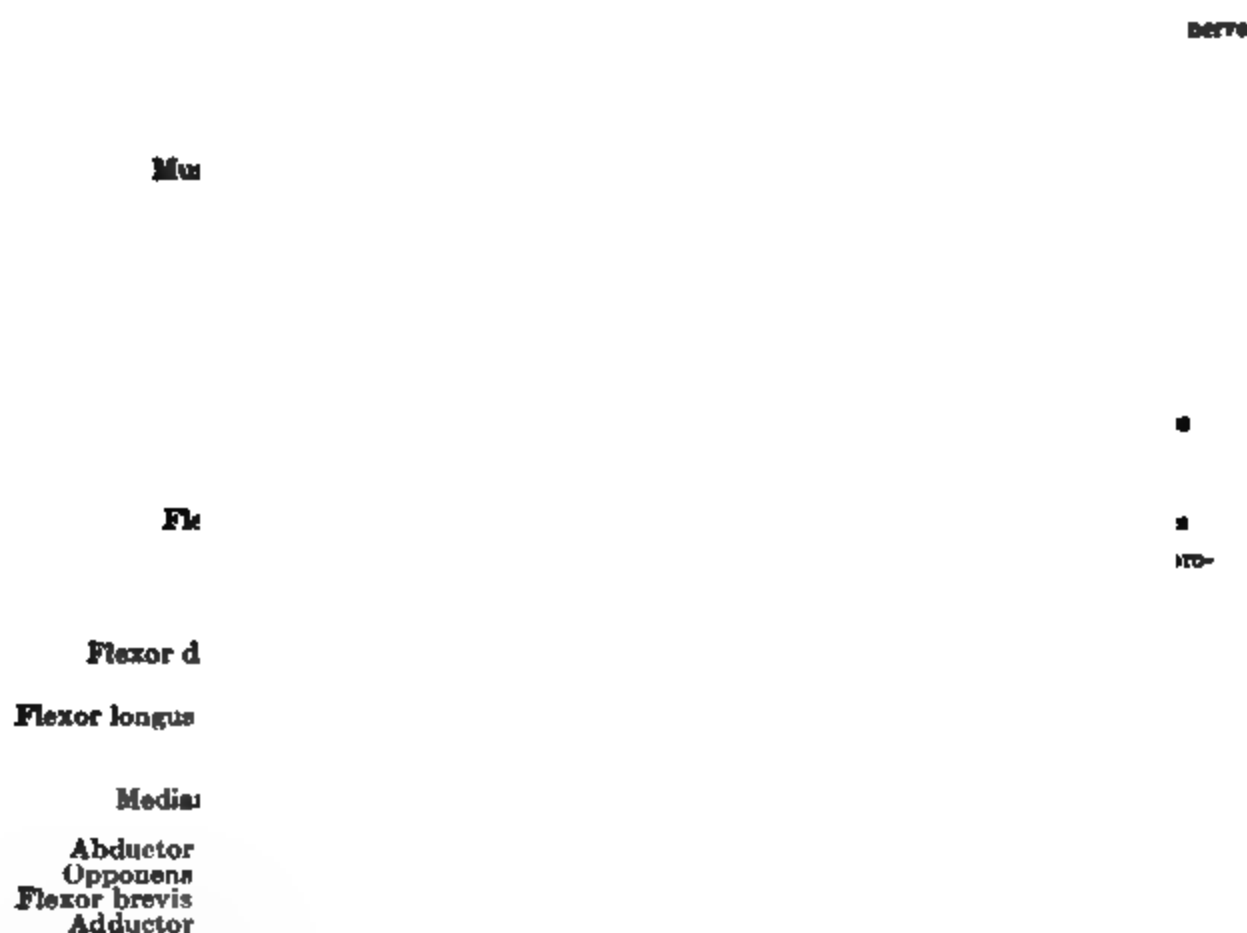

Fig. 391.—Motor points on the anterior aspect of the arm.

latter becomes quiet. In a well-made instrument adapted for medical purposes, with a good rheostat, this will occur in a few seconds.

¹ This point should be sought for in the external bicipital groove at the junction of the middle and lower thirds of the arm. According to Erb, it is midway between the external condyle and the insertion of the deltoid. It is frequently difficult to locate, because the nerve easily rolls from beneath the electrode, and possibly also because the electrode is lifted away from the nerve by the contraction of the biceps and triceps. A very small electrode should be employed for this examination. It should be noted that the trunk of the musculospiral nerve may also be irritated in the axilla at the inner border of the upper extremity of the coracobrachialis. Erb's point (see Fig. 390) may also be employed for the supinator longus. These points possess a special clinical interest, as will be shown on p. 1031.

Dubois (Bern) ¹ has recently shown, however, that in estimating the galvanic irritability of a nerve or muscle it is more accurate to make the calculation in volts than in ampères, for the same movement of the muscles always takes substantially the same voltage, while the current rises with the resistance interposed. This coincides with the experience

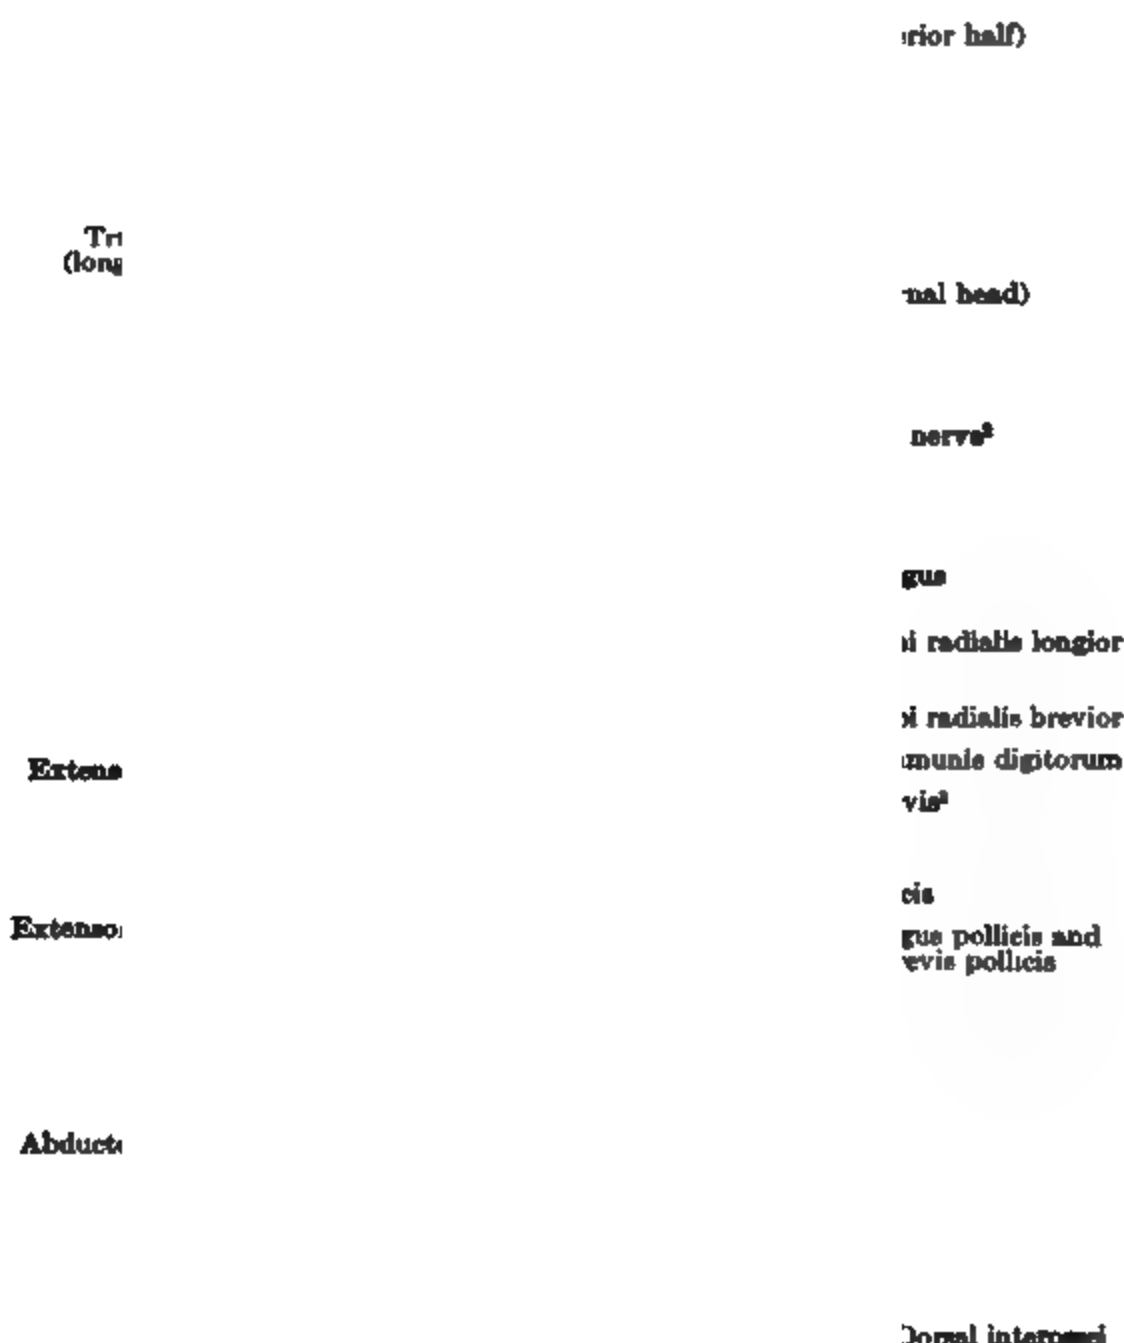

Fig. 392.—Motor points on the posterior aspect of the arm.

of Cornaz,⁴ one of his pupils. He found that the measurements made in volts conformed much more nearly than those made in ampères when he tested the same nerve of the same individual at different times,

¹ Arch. de physiol., October, 1897.

² See note to Fig. 391.

³ It is possible to irritate the supinator brevis by itself only when the extensor communis digitorum is atrophic and fails to respond to the electric current (as in lead palsy, for example).

⁴ I. A. Diss., Bern, 1898.

or similar nerves of different people, or similar nerves of the two sides of the body. Dubois explains this phenomenon by the following fact, which he established experimentally (for the details his monograph must be consulted): The resistance of the human body, in consequence of its great "capacity," has practically no influence on the amount of stimulation, which depends upon potential. So that if the metallic resistance

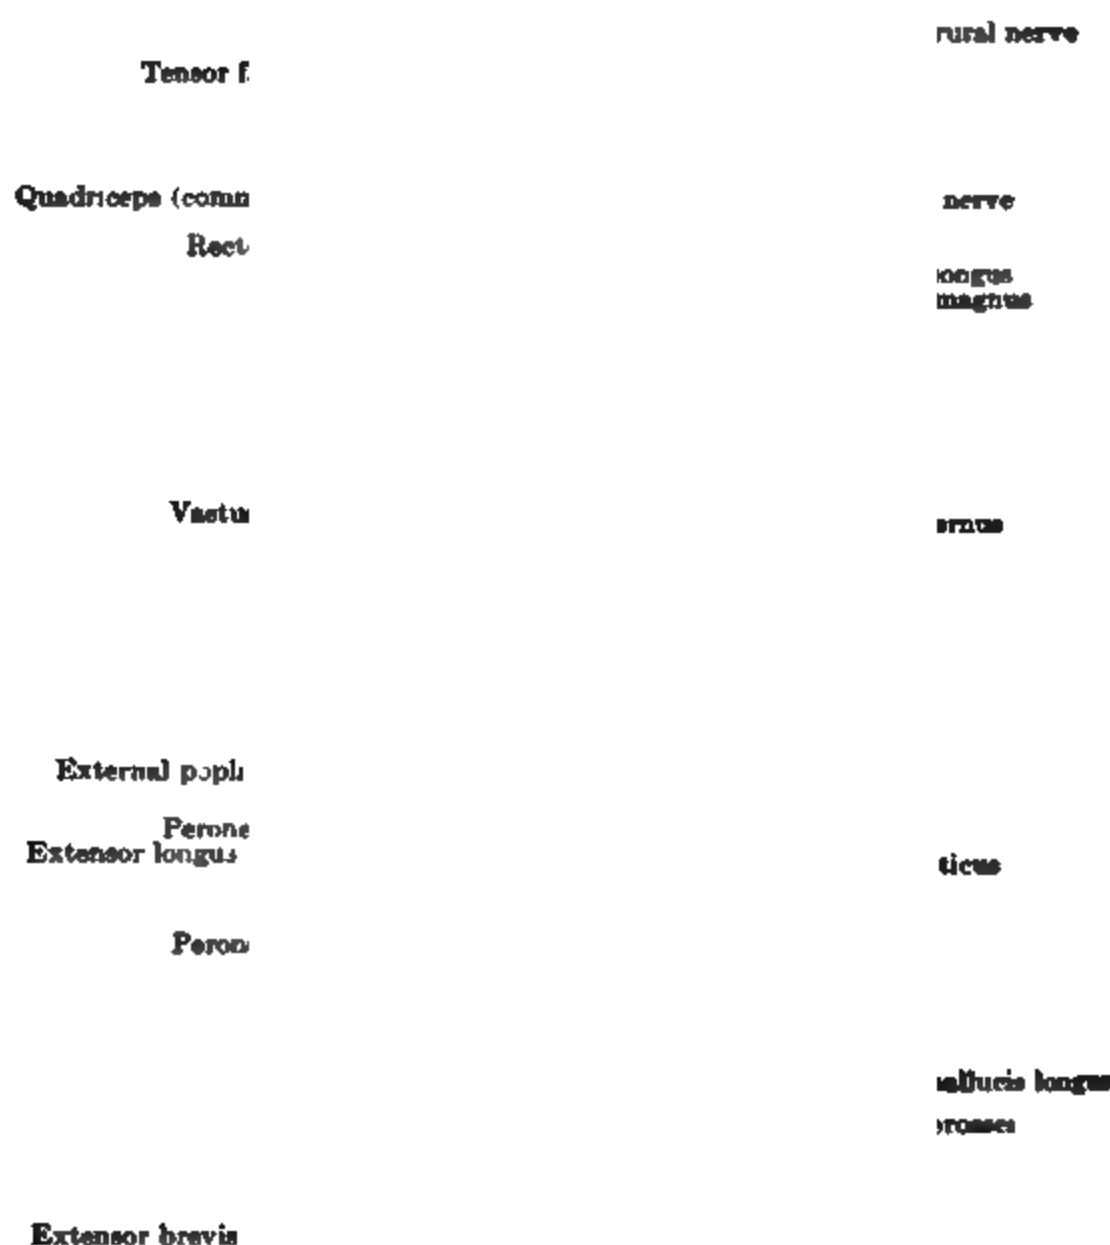

Fig. 393.—Motor points on the anterior aspect of the leg.

of the current circuit do not change, and if the current strength vary only with alterations in the electromotive force, the stimulation can be determined with considerable accuracy by the volt tension. To be sure, this is no longer the case if rheostat resistance be interpolated into the main circuit and the action of the current is thus graded, as was formerly the custom in electrodiagnosis. Dubois has shown that such resistance, whether fluid or metallic, produces strong auto-induc-

tion. Therefore it must cause a change not only in the current strength, but also in the increase of the current. Under these conditions neither the volt tension nor the current strength can be considered a measure of the irritative effect, so that this old procedure loses its value. Examining the same muscle repeatedly with the same strength of current,

Fig. 394.—Motor points on the posterior aspect of the leg.

but with varying rheostat resistance, would therefore explain many previously inexplicable contradictions in electrodiagnosis.

Hence, in employing the voltmeter it is advisable to regulate the galvanic apparatus so that the resistance in the main current will not vary with a gradation of current activity. In other words, in addition to the employment of the element transformer, the current activity

should be graded only by altering the volt tension. The latter effect can be accomplished by inserting a rheostat into the lateral circuit, or, still better, by Gaiffe's "reducteur de potentiel," constructed according to the principle of the rheochord.

Instead of the galvanometer, Dubois recommends substituting the voltmeter, combined with the "reducteur de potentiel," for electrodiagnosis (though not for electrotherapy). The voltmeter is practically a galvanometer situated in the lateral circuit, but of so great a resistance that the resistance of the Battery does not enter into consideration. Gaiffe's instrument is especially serviceable for electrodiagnostic purposes, because a simple alteration will in a few seconds change it to a galvanometer with *accurate divisions*. The voltmeter possesses another great advantage. Its needle does not oscillate with the opening and closing of the current, so that the reading may be made during the examination. This is much more trustworthy than the estimation of the current strength, which can be read only after the stimulation is finished or with the opening stimulation before it begins.

This combination of voltmeter with "reducteur de potentiel" has been used at the author's clinic as long as batteries¹ have been employed, and has been entirely satisfactory.

It should be noted that the accuracy of the measurement of galvanic reaction by means of the voltmeter has recently been questioned by Mann,² who recommends, as the method most free from objection, the employment of condenser discharges. Since this method has not yet been extensively employed, the author will simply refer the reader to Mann's article, and also a later monograph by Zanietowski, *The Condensor Method*, Leipzig, Barth, 1906.

The condensor method causes much less pain than the galvanic test on account of the short duration of the current and the absence of electrolytic effects. It would be an especially desirable substitute in those cases of peripheral paralysis where, because of greatly lowered excitability, very strong galvanic currents are necessary. The investigations undertaken by the author in the interest of electrotherapy rather than diagnosis have shown that the condenser stimulations act incompletely if the excitability be *low*, *i. e.*, fail to excite contractions that might still be produced by the galvanic current. Dubois has shown that if the excitability be normal, a condenser of one microfarad with about the same voltage causes a contraction similar to that of the galvanic current.

The induction current, as Dubois has shown, has faults, even with the modern simplified gradations of the apparatus. Unfortunately, it must be confessed that thus far no method has been devised to estimate the physiologic action of the induction current in a universally efficient way, *i. e.*, in figures independent of the apparatus employed. The physiologic action of one induction apparatus cannot be compared with the action of another, so that for quantitative examination or for comparison of results we should always employ the same apparatus and the same primary voltage. In case cells are used for the induction apparatus it is necessary to have always the same number (2 or 3) of Leclanché or Bunsen elements. If the induction apparatus be connected with the street current, the amount must be set at a definite voltage. The distance that the secondary coil is moved will measure the current strength; provided, of course, that the elements or cells are freshly prepared. Since the individual centimeters of the scale usually placed upon the induction apparatus correspond to entirely different

¹ At the present time a Klingelfust apparatus connected with central storage batteries is used.

² Berlin. klin. Woch., 1904, No. 33.

variations in the effect of the current, it would be much better to graduate the scale also in absolute units, according to the method of Kronecker.¹ It must not be supposed, however, that such a graduation will enable us to compare different induction apparatuses, since the rapidity of increase in the individual induction currents, and their consequent irritating effects, are quite different, being dependent upon the quality of the coils as well as upon the electromotive force of the elements which run the apparatus. The absolute graduation simply possesses the advantage that, if we always use the same machine with freshly prepared elements, we obtain a better idea of the effect of the current.

Even with a faradic current the bodily resistance varies physiologically, because the stimulation takes place under variable conditions in a circuit of great capacity; but such variation does not produce any decided difference in the effect of the stimulation any more than with galvanism (see above). Therefore it seems unnecessary to follow the advice of some writers and measure the skin resistance galvanically, as well as the distance of the secondary coil, when applying the faradic current. But in any event the electrodes must be well moistened, in order that the contact may be as complete as possible.

It is quite as important, in determining the dosage of the faradic as in determining that of the galvanic currents, to employ electrodes of definite size; because, naturally, the intensity with which the current impinges upon a given spot is quite as important as the current strength and the voltage. The current intensity is equal to the current strength divided by the square surface of the electrode. Therefore, under otherwise equal conditions, an electrode of 2 sq. cm. surface provides only half as great a stimulation effect as one of 1 sq. cm. surface. Such an estimation is accurate only for the skin surface directly in contact with the electrode. In penetrating the skin the current is, of course, diffused over a much greater area, and since most of the muscles and nerves to be stimulated lie at a certain depth, the size of the electrode is in reality not so important as implied by this calculation. At all events, in order that the conditions may be kept as constant as possible, electrodes of the same size should be employed in comparative examination, and their dimensions should be mentioned in the description. The so-called "normal" electrodes (p. 1011) are the most satisfactory.

The technic of applying the electrode is naturally important, for a larger electrode set against the body surface at an angle naturally acts like a smaller one. Again, one-sided pressure should be avoided, the pressure should not crowd the soft parts too much, and the well-moistened surface of the electrode should be in intimate contact with the body.

If, as is sometimes the case, especially in employing a portable galvanic battery, we wish to differentiate the poles quickly, it can be done very easily by grasping the electrodes, one in each hand, and then estimating which electrode causes more intense burning on closing the current. The one that does will be the cathode. Of course, the electrodes should be of the same size and equally well moistened. Again, the cathode turns moistened violet litmus-paper blue; the anode turns it red. With the faradic current a stronger irritation is produced by a cathodal opening, and after the passage of some current a blue spot will appear upon the litmus paper. The opening of the induced current, on

¹ Zeits. f. Instrumentenkunde, 1889.

account of its greater strength, is of chief importance for the collective action of the alternating stream.

The electrode to be employed in such tests should be of polished metal; for this will give sufficient current strength for the slight electrolytic action of the induction current; and we need not fear any discoloration of the litmus paper by the acid metallic salts which always collect upon old electrodes.

The following abbreviations are employed to tabulate the results of an electric examination:

X mm. D = distance in millimeters that the secondary has been withdrawn from the primary coil.

M.A. = milliamperes.

V. = volt.

Ca.C.C. = Cathodal closure contraction.

An.C.C. = Anodal closure contraction.

An.O.C. = Anodal opening contraction.

Ca.O.C. = Cathodal opening contraction.

Ca.C.T. = Cathodal closure tetanus.

Ca.C.C. = 2 *M.A.* signifies that a minimal cathodal closure contraction will be produced by 2 milliamperes of current.

Far. C. 90 mm. D. signifies that a minimal faradic contraction will be excited when the secondary coil is withdrawn 90 millimeters.

Ca.C.C. > An.C.C. signifies that the cathodal closure contraction is greater than the anodal closure contraction, etc.

2. METHOD OF TESTING THE QUANTITATIVE ELECTRIC IRRITABILITY OF THE NERVE MUSCLE

We test the quantitative electric irritability of a nerve or of a muscle by estimating how strong a galvanic, and then how strong a faradic, current is required to produce a minimal contraction. (See p. 102 et seq.) With a galvanic current the cathodal closure contraction is normally the easier to obtain; hence, it is ordinarily employed for this estimation. When a maximum current produces no further contraction, the condition is called exhausted irritability. Since this condition holds good only for that particular maximum current strength or volt tension employed, it is advisable to determine and note both of them.

Physiologically, the irritability of different nerves and muscles, as well as that of the same muscle or nerve, varies considerably in different individuals. It is not by any means easy, therefore, in any given case to determine whether the results of the examination overstep the normal limits, and, if so, how much. The following method seems the most practical: We estimate the irritability and then compare it with that of a healthy person, or, if the disturbance be unilateral, with that of the healthy side. The latter is, of course, always more accurate. Symmetric points and an identical position must, of course, be selected. Erb and Stintzing have shown that the normal differences in irritability upon the two sides are very slight. In comparing the results with those found in a healthy person, decided differences only should be regarded as significant.

Galvanic Current

Normal Estimations to be Used in Comparing the Galvanic Irritability of the Two Sides.—The following figures represent the maximal differences of the galvanic current strength which is needed to stimulate actively the normal nerve of both sides of the body. They are copied from Stintzing, and were estimated with his normal electrode of 3 sq. cm.:

Maximal Physiologic Differences between the Galvanic Irritability of the Two Halves of the Body Expressed in Current Strength. (After Stintzing.)

Ramus frontalis of the facial nerve.....	0.7	M.A.
Nervus accessorius.....	0.15	"
Nervus medianus.....	0.6	"
Nervus ulnaris (2" above the olecranon).....	0.6	"
Musculospiral nerve.....	1.1	"
Nervus peroneus.....	0.5	"
Nervus tibialis.....	1.1	"

The following figures show that the voltage rates, according to Dubois and Cornaz, are more conclusive. These writers found, after many examinations:

Rates of Voltage Which are Required for a Minimal Stimulation of the Corresponding Normal Nerves of the Two Sides of Body.

Facialis (maxim.)	100 : 122	(corresponding ratio of current strength = 100 : 129)
Medianus	" 100 : 117	(" " " = 100 : 503)
Musculospiral	" 100 : 112	(" " " = 100 : 145)
Ulnaris	" 100 : 116	(" " " = 100 : 253)
Peroneus	" 100 : 130	(" " " = 100 : 175)

Normal Estimations to be Used in Comparing the Galvanic Excitability of Different Individuals.—The following figures represent the averages which Stintzing computed from an examination of 58 healthy individuals. They are useful when we cannot compare the two sides of the body:

Limits of the Normal Irritability Expressed in Current Strength. (After Stintzing.)

When a weaker current strength or voltage excites a minimal contraction, the excitability is increased; when a stronger one is required, the excitability is diminished.

As mentioned above (see p. 1015), the measurement by voltage is the more accurate method, *e. g.*, a minimal voltage which will produce the necessary stimulation will correspond to a much greater current strength if the resistance be slight than if the resistance be high (according to p. 1016 et seq.). The milliampère value will, in the former case, conceal a diminished, and, in the latter case, an increased, excitability.

Faradic Current

Every examiner will gradually become accustomed to his own apparatus, so that he knows what differences come within physiologic limits. Stintzing found that with his own apparatus the maximal physiologic difference for all nerves examined was 15 mm. D. This is a rather indefinite statement; since this 15 mm., even with Stintzing's apparatus, corresponds to entirely different amounts of irritation, dependent upon the position of the secondary coil, and these values, moreover, do not obtain when another apparatus is employed. Differences which exceed a physiologic maximum should be regarded as pathologic. If a shorter distance be necessary to excite a minimal contraction, it shows a diminution of irritability; if a greater distance be required, an increase of irritability.

3. METHOD OF TESTING THE QUALITATIVE ELECTRIC EXCITABILITY OF THE NERVE MUSCLE

The irritability of motor nerves is subject only to quantitative alteration. But with the muscles, quantitative changes are often accompanied by qualitative alterations, which require a special description.

(a) Normal Conditions

The qualitative normal reaction of motor nerves and muscles to a galvanic stimulation is expressed in the following so-called law of contraction:

The Normal Law of Contraction for the Motor Nerves with a Galvanic Current.

WEAK CURRENT

Ca.C.C.....An.C. : no effect.
Ca.O. : no effect.....An.O. : no effect.

MODERATE CURRENT

Ca.C.C. : vigorous.....An.C.C. : weak.
Ca.O. : no effect.....An.O.C. : weak.

VERY STRONG CURRENT

Ca.C.T.....An.C.C.: vigorous.
Ca.O.C.: variable.....An.O.C.: vigorous.

The normal law of contraction for the muscles with a galvanic current differs from the above only by the fact that the opening contraction is either obtained with great difficulty or, more commonly, cannot be produced. The contraction of a muscle to galvanism, whether the muscle be stimulated directly or indirectly through the nerve, normally appears

very suddenly. Yet some differences occur, depending upon whether the differential electrode be applied to the motor point of the muscle or at some distance from it. The latter (avoiding the motor point as far as possible) is the only way in which we can excite a pure muscular contraction. Although sudden, the contractions are somewhat less lightning-like, and the distinction between *Ca.C.C.* and *An.C.C.* is less pronounced. A stimulation from the motor point itself should be regarded as the stimulation of a nerve. In case the nerve excitability is not lost, we must consider stimulation of a motor point in reality a nerve stimulation. In spite of this, the excitability of a motor point is usually designated in electrodiagnosis as muscular excitability.

Normal Laws for Contraction of Motor Nerves and Muscles with the Ordinary Faradic Current (the Rapidly Interrupted and Alternating Induced Current).—Faradic stimulation of both muscle and nerve is tetanic, i. e., as soon as *D.* (the distance) is diminished enough to produce any contraction at all, the muscle remains contracted so long as the alternating current flows through it or through its motor nerve. The onset and the cessation of the tetanic muscular contraction correspond to the closure and the opening of the current, and are sudden and lightning-like. The two poles of the faradic current differ only in their quantitative effect, i. e., the pole at which the opening induction current has its cathode is somewhat stronger. The faradic current, when applied at some distance from a motor point, produces a much weaker contraction than when applied directly to it. Qualitatively, on the contrary, the effect is identical.

(b) Pathologic Conditions

Reaction of Degeneration (R. D.).—The essential factor in the reaction of degeneration which occurs in peripheral and nuclear paral-

(a) Healthy girl. *Ca.C.C.* decidedly greater than *An.C.C.* Contraction lightning-like.

(b) Poliomyelitis reaction of degeneration. *An.C.C.* much greater than *Ca.C.C.* Contraction slow.

Fig. 395.—Myographic curves of galvanic closure contraction from a direct muscular stimulation in the peroneal region. (a) Normal; (b) reaction of degeneration (taken from Kast).

yses is the condition of the muscles (see p. 1029 et seq. in regard to its significance). This reaction, in the broadest sense of the term, presents very different modifications. The two cardinal symptoms common to all forms are the following:

1. The essentially different reaction of the muscle to prolonged and to transitory stimulation, that is, to galvanic and faradic. The muscle

(a) Paralysis with a relatively early recovery of the motility.

(b) Paralysis with a later recovery of the motility.

(c) Irreparable paralysis. Disappearance of motility persists.

Fig. 396.—Diagram of the course of irritability in peripheral paralysis with complete resection of degeneration: The wavy character of the line which represents the galvanic irritability signifies that the irritability is qualitatively modified, i. e., there is a R. D. Where the line is even, the condition is qualitatively normal. The asterisk marks the return of voluntary motility. The histologic changes in the nerve and muscle are printed at each stage above the curves. The figures above the curves correspond to the number of weeks which have elapsed since the onset of the paralysis. The abscissa of the later course of the paralysis had to be shortened in different degrees for the three curves on account of the space, so that the curves cannot be exactly compared as to their length (Erb).

either does not react at all to the faradic current, or its reaction is very much weaker than to the galvanic current. Dubois's experiments, how-

ever, show that single shocks of a very strong current will often produce a contraction, even where the reaction of degeneration is complete. He believes that rapidly succeeding shocks, *i. e.*, with a freely vibrating hammer, so fatigue the muscle that it cannot contract.

2. The contraction no longer exhibits a lightning-like character, but is slow and vermiform. An after-contraction may sometimes persist after the original effect has ceased; and in a pronounced example a tetanic contraction will be excited which will persist most of the time while the current is applied.

The other characteristics of the reaction are very variable; they will be mentioned below.

The two peculiarities just outlined are common to all forms of reaction of degeneration, and are to be regarded as the clinical expression of a degenerative atrophy of the muscle due to some peripheral lesion. (See p. 1029 et seq.)

The complete reaction of degeneration may be schematically described as follows:

Faradic test: Excitability of the nerves lost.

Faradic test: Excitability of the muscles lost.

Galvanic test: Excitability of the nerves lost.

Galvanic test: Excitability of the muscles immediately after the onset of the paralysis quantitatively normal, later increased, and finally often decidedly diminished. The contraction is slow. Myobradia, *An.C.C.* is excited more rapidly than *Ca.C.C.* $An.C.C. > Ca.C.C.$ for the same current strength or voltage.

The myographic curves (Fig. 395) illustrate these quantitative changes of the muscle reaction.

The duration of complete reaction of degeneration in peripheral paralysis is very typical. It has been studied thoroughly in severe facial paralysis of rheumatic origin, and has been graphically represented by Erb (Fig. 396).

Mechanical reaction of degeneration, mentioned upon p. 1009, occurs principally where there is complete electric reaction of degeneration with increased irritability.

Partial (Incomplete) Reaction of Degeneration.—In this form the faradic and galvanic irritability of the nerves and the faradic irritability of the muscles are not lost, but merely diminished. A slow contraction is ordinarily caused only by galvanic excitation of the muscles, although sometimes faradic excitation with isolated shocks at some distance from the motor point will produce the same effect. A scheme of the incomplete reaction of degeneration follows:

Faradic:	}	Irritability merely diminished. Contractions not slower except sometimes in the case of the faradic muscle contraction when the motor point is avoided.
Nerve		
Muscle.		
Galvanic:		
Nerve.	}	Far from motor point like the complete reaction of degeneration.
Muscle.		

The course of an incomplete reaction of degeneration in peripheral paralyses is represented in Fig. 397.

Incomplete Reaction of Degeneration with Compulsory Indirect Sluggish Contractions.—In this form, as distinguished from the simple incomplete reaction of degeneration, all the contractions are slowed, not only those excited by galvanic muscular stimulation, but also those excited by faradic stimulation of the muscles and by faradic or galvanic stimulation of the nerves.

Mixed Reaction of Degeneration.—When some of the fibers of a muscle preserve a normal reaction, while others present a reaction of degeneration, the result is called a *mixed reaction of degeneration*. In such cases we cannot examine each type of fiber separately, so that the resulting mixed reaction is frequently difficult to understand, and it is quite impossible to pick out which of the fibers show a normal reaction and which a reaction of degeneration. Many instances of incomplete reaction of degeneration really belong to this variety.

Alternating Contractility.—E. Rautenberg has recently found a remarkable phenomenon of alternating contractions, i. e., varying coarse and fine contractions with an equal amount of current in peripherally affected muscles (muscular atrophies and peripheral palsies) which did not show reaction of degeneration. These muscles under faradic stimulation (single interruptions and tetanizing stimulation) showed an abnormal fatigue, the contraction during frequently repeated stimulation diminished more quickly than normally, and under certain conditions disappeared entirely. Where a tetanizing stimulation was used, there appeared also a lengthening of the latent period of stimulation. This alternation of weak and strong contractions is interpreted by Rautenberg as a disturbance of contractility and analogous to the *pulsus alternans* of the heart. (See p. 162.) He does not discuss its diagnostic significance nor its presence in different diseases of the muscles.

Peculiar Electric Reactions of Certain Old Peripheral Palsies.—Placzek,¹ and subsequently Bernhardt,² have described a peculiar phenomenon which is in

Fig. 397.—Diagram of the course of irritability in partial reaction of degeneration. See the explanation of Fig. 396. The faradic and galvanic irritability of the nerves and the faradic irritability of the muscles are only slightly diminished. Motility returns early. Compensation early and complete. Nerve degeneration probably absent.

rare cases observed as a termination of severe peripheral facial palsies. In contrast to the usual findings, the electric reactions of the nerve muscle in some of these old facial palsies reappear, although the paralysis of voluntary motion remains permanent. This phenomenon is highly interesting from a theoretic standpoint, and the author would regard it as analogous to the behavior of the so-called mild peripheral palsies, in which the paralysis of voluntary motion exists together with maintained electric excitability of the peripheral parts. Both conditions may be explained only by the supposition that changes exist in the peripheral nerves which block voluntary impulses, but do not disturb the peripheral excitability of the nerve or muscle. In the old palsies exhibiting this phenomenon there can be no doubt that peripheral regeneration has taken place, but that the blockading of voluntary impulses nevertheless permanently remains. This is difficult to understand if we cling to the old theory of the necessity of efferent irritations for the trophic integrity of the nerve muscle. This old theory, however, does not seem to obtain in all cases, since Bethe has shown that, when the union of divided nerve-fibers is prevented in young animals, a peripheral regeneration may nevertheless occur, so that the nerve-fibers regain their electric irritability. Under the conditions mentioned above, reflex impulses which maintain the muscle tonus and preserve the vitality of the nerve and muscle in the periphery, might also be conceived to

¹ Berlin, klin. Woch., 1893.

² Ibid., 1903.

pass the obstacle. As far as the author knows, this question has not been investigated.

Myotonic Reaction (Erb).—This occurs only in Thomsen's disease (*myotonia congenita*). It is characterized by a peculiar persistence of the contraction after the cessation of the stimulation. The contractions are sluggish, and, when the galvanic current is steadily applied to the muscles, are often characteristically rhythmic and wave-like (*galvanic myokymia*). Even very weak currents will excite these phenomena (*muscle hyperirritability*). The anodal closure contraction (*An.C.C.*) of the muscle is frequently more vigorous than the cathodal closure (*Ca.C.C.*). Theoretically, it is of interest to know that, according to Panzini (ref. in *Sem. méd.*, 1908, No. 15, p. 175), the muscles of new-born mammals, the normal muscles of the toad, and, furthermore, muscles poisoned by veratrin, digitalin, hellebore, oxalic acid, and sodium salts give a myotonic reaction.

Neurotonic Reaction.—A few years ago Marina¹ and Remak² independently described a rare form of reaction which they called *neurotonic reaction*. Marina found it in *hysteria*, and Remak in a case, in all probability, of *progressive muscular atrophy*.

In this reaction, without any increase of the quantitative minimum irritability, anodal opening contraction appears very early from stimulation of the nerve, but not of the muscle. There is also a special tendency of the nerve to cathodal closure and anodal opening tetanus. The closure tetanus can be prolonged beyond the opening of the current, and the faradic tetanus of the nerve persists after stopping the stimulation. These characteristic phenomena depend essentially upon nerve irritation, and they cannot be excited by stimulation of the muscle.

Reaction in Tetany and Spasmophilia.—A quantitative increase of the electric irritability of the nerve-trunks is usually found in these conditions, although it does not affect the muscle, or, at least, not nearly to so great an extent. The quality of the reaction of the nerve is frequently, though not constantly, altered, *e. g.*, a neurotonic reaction appears with a tendency to anodal opening and cathodal closure tetanus and a prolongation of the contraction. The essential difference is that in tetany, as contrasted with neurotonic reaction proper, a quantitative increase of irritability accompanies the qualitative changes. The electric reactions of tetany are also found in the eclampsias of little children. These conditions, including *spasmus glottidis*, have, therefore, under the name of *spasmophilia*, been brought into close relationship with tetany or disturbances of the function of the parathyroids. When utilizing this reaction for the diagnosis of *spasmophilia* in little children, it must be remembered that, on account of the thickness of the subcutaneous fat, a stronger current must be employed for them than is usually necessary for adults.

Characteristic Reaction in Certain Traumatic Neuroses.—Rumpf³ has used the term "traumatic reaction" for this peculiar phenomenon. For some time after the cessation of a vigorous faradic stimulation the muscle will exhibit a characteristic fluctuating movement, made up of alternating fibrillary and clonic contractions (*faradic myokymia*). In certain cases these complex results occur even during the stimulation. Each contraction may spread from the muscle which is directly stimulated and become generalized. In these patients similar appearances are observed to follow vigorous efforts and the action of cold. (See p. 957, *Fibrillary Contractions in the Healthy*.)

Myasthenic Reaction.—A peculiar electric condition of the affected parts accompanies *myasthenia gravis pseudoparalytica* or *asthenic bulbar paralysis*, as the disease is usually called. It was first described by Jolly.⁴ When a tetanic induction current is permitted to act upon a muscle, whether directly or through the nerve, the contraction gradually diminishes and finally disappears. This electric phenomenon is entirely analogous to the pathologic fatigue of the muscle after voluntary impulses, which is so characteristic of this disease, and it represents a higher degree of the faradic "fatigue" than can be demonstrated in health or especially in paralyzed muscles. A similar phenomenon can be elicited experimentally in muscles poisoned with protoveratrin.⁵ The myasthenic reaction (diminution of contraction with increasing fatigue) is seen usually with a tetanizing current only, not with single interruptions. E. Rautenberg has recently described⁶ a number

¹ See *Neurol. Centralbl.*, 1896, No. 17. Marina's older publications upon this subject are mentioned here. ² *Neurol. Centralbl.*, 1896, No. 13.

³ *Deut. med. Woch.*, 1890, No. 9, p. 165.

⁴ *Berlin. klin. Woch.*, 1895, vol. i, p. 2, et seq.

⁵ Prognosis will be discussed separately upon p. 819, et seq.

⁶ *Deut. Arch. f. klin. Med.*, 1908, vol. xciii.

of new and interesting phenomena in myasthenia. 1. The muscle shows a remarkably sluggish reaction (myobradia) similar to the reaction of degeneration. At the commencement of the stimulation with short tetanizing currents the height of the curve increases gradually, just as in a normal muscle ("steps" of Bowditch). 2. Under continued stimulation the curve becomes progressively lower and more sluggish (true myasthenic reaction). 3. In this stage of fatigue the contractions are of unequal form and height and often of a peculiar behavior, in that the muscle becomes more and more emancipated from the stimulation, the contraction becoming at first delayed and finally quite independent of the stimulation (myautonomy). The explanation of this phenomenon is as follows: 4. The muscle is unable to respond to more frequent stimulations by superposition of contractions, as a normal muscle does, so that the number of stimulations to which it is able to respond with the regular contractions is limited by the length of the contraction; and 5. As soon as the muscle is stimulated by more than two or three short tetanizing or four or five very powerful stimulations to the second, even in the fatigue stage, it enters into a stage of irritation and contracts rhythmically. In this stage the muscle no longer shows a diminution of the contraction, a true myasthenic reaction. The contractions are, however, even more sluggish than usual. 6. In this stage the muscle has become refractory toward other, including much more powerful, stimulations. 7. The muscle having once reached this stage, sometimes a lessened or altered frequency of stimulation will suffice to maintain it in this state of irritation. One or two contractions may even take place after cessation of the stimulation, the state of irritation persisting after the stimulation. This last-named phenomenon of muscle autonomy is not identical with the myokymia, which appears in myotonia and traumatic neurosis. (See p. 1027.) It is not a muscle-wave, but a powerful rhythmic contraction of the whole muscle, with a complete emancipation of the same from the stimulation; in other words, a behavior which suggests that of the cardiac muscle. Rautenberg, in closing, points out that these phenomena are not constant in myasthenia. The author has seen the same manifestations in a case of alcoholic neuritis.

4. DIAGNOSTIC SIGNIFICANCE OF THE DIFFERENT ELECTRIC REACTIONS¹

The myotonic, neurotonic, "traumatic," and tetany or spasmophilia reactions have been sufficiently described above, and, so far as our present knowledge goes, each is limited to its corresponding disease.

In *psychic* or *hysteric paralysis* the electric irritability remains normal. This is also a general rule for all paralyses which depend upon a lesion of the voluntary tracts above the nucleus, *i. e.*, above the gray anterior horn (*cerebral hemiplegias, transverse lesions of the spinal cord*). Sometimes, however, in these cases, especially if the paralysis has persisted for some time, the electric irritability is considerably diminished.

The condition during the first few days following a *peripheral paralysis* (see Figs. 396 and 397), and that during the entire course of the *milder forms*, will illustrate very typically a simple diminution in the electric irritability. Diminished irritability is almost invariably associated with electric exhaustibility, which is manifest by the decidedly lessened response or absence of response during a long-continued repeated stimulation to currents which at first induced vigorous contractions. When the peripheral interruption of conduction is complete, *i. e.*, when the paralysis is severe, reaction of degeneration will generally take the place of simple diminution of irritability.

Some cases of *polyneuritis* and of *lead-poisoning* furnish striking exceptions to the above statements. In some cases, instead of the expected reaction of degeneration, not only is the irritability diminished, but the diminution is so pronounced that even direct contact of the galvanic current excites no response. This proves that in these cases the muscles are affected by the toxins directly, and not alone through

¹ The electric diagnostic prognosis has a special chapter, p. 1031.

involvement of the nerve. In fact, there are many other reasons for such a hypothesis. This supposition is most probable in those cases which recover, despite a marked diminution of the direct galvanic muscular irritability. In curable cases of polyneuritis and lead-poisoning, however, the disappearance of the galvanic irritability, especially if it occur late in the disease, must be regarded as the terminal stage of R. D., and the expression of definite secondary degeneration of the muscle. (See Fig. 396 c, p. 1024.)

In the *myopathic forms of progressive muscular atrophy* simple diminution of electric irritability is the rule.

A simple increase of electric irritability is a comparatively rare phenomenon. It is seen in very recent neuritic paralyses and in tetany, or in that condition probably near akin to it—the so-called spasmophilia of young children. (See p. 1027.) It then depends chiefly upon nerve excitability. Increased excitability of the nerve or muscle, with coincident qualitative change, should not be confused with such a condition. (Reaction of Degeneration, Myotonic Reaction, Tetanic Reaction, see above.)

The various alterations in the reaction of degeneration (in the widest sense of the term) occur only in cases in which the muscle is affected by a break in conduction between it and its so-called trophic center¹ (situated in the nucleus, *i. e.*, in the anterior horns), or where a lesion of the center itself occurs, or where the muscle is primarily degenerated. The degeneration of the muscle, and with it the reaction of degeneration, may be absent, even when the lesion is so situated, provided it be slight and transitory. Degenerative changes in the muscle are found in all instances of reaction of degeneration, and, in fact, seem to be the physiologic expression of such a reaction. If complete, the degeneration also spreads to the nerve. A partial reaction of degeneration, on the contrary, which is observed in a moderately severe disturbance of conduction, is a sign of a degeneration of the muscle with normal, or, at most, only slightly degenerated, nerves. The retention of nerve irritability in partial reactions of degeneration seems to depend upon the preservation of the medullary sheaths.

The most frequent lesions which produce the various types of the reaction of degeneration are, therefore, *nuclear* or *peripheral paralyses*. The *spinal* and the *neuritic muscular atrophies* also often lead to partial reactions of degeneration. Yet numerous variations in the electric reactions occur in individual cases of these muscular atrophies, because in them, as contrasted with actual paralyses, each fiber is successively and, in a certain measure, individually diseased. Therefore each muscle we examine contains a series of fibers in different conditions of irritability, and the resulting reaction will depend upon whether seriously injured, slightly affected, or intact fibers predominate. In *spinal* and *neuritic muscular atrophies* a *mixed reaction* is the rule, whereas a *partial or complete reaction of degeneration* is much commoner in *peripheral palsies*.

Many cases, however, of spinal or neuritic muscular atrophies show absolutely no signs of reaction of degeneration as, *e. g.*, if the fibers which are seriously affected be very rapidly and quite completely destroyed, so that the reaction to stimulation actually comes from intact fibers or from those only slightly affected, and is merely quanti-

¹ See p. 1001, note 1, for the significance of the trophic character of this center.

tatively diminished. We might call this result, which is by no means uncommon in spinal and neuritic muscular atrophies, a sort of latent reaction of degeneration. The same peculiarity is presented in *bulbar paralysis*, which in its origin is identical with the *spinal form of muscular atrophy* and with the closely related *amyotrophic lateral sclerosis*. Reaction of degeneration may or may not be present. The *myopathic forms of muscular atrophy* exhibit similar variations. Although it is perfectly true that most cases exhibit no R. D., still a suggestion of such a reaction may occasionally occur even in the myopathic forms. This apparent inconsistency may depend upon the presence of many seriously affected fibers which still react to stimulation at the time of the examination. If many such fibers be present, reaction of degeneration will result; if, on the other hand, the fibers are quickly destroyed, the normal or simply diminished reaction of the unaffected fibers will persist. The occurrence of such variations (*i. e.*, reaction of degeneration in purely myopathic forms, and, conversely, its absence in spinal and neuritic forms of muscular atrophies) shows that we must not rely upon the electric examination to decide the form of the muscular atrophy, but turn to other clinical evidence, such as heredity, age, mode of extension of the disease, etc.

Fig. 398.

From what has been said, it is plain that it is much more important for diagnosis to demonstrate that the reaction of degeneration is present than that it is absent. A *positive reaction of degeneration* (this is perhaps the most important law in electrodiagnosis) *absolutely excludes a central or supranuclear origin* for the disease. The absence of reaction of degeneration, however, even if we except the cases where the lesion is too slight to produce it, does not always permit the exclusion of a nuclear or subnuclear cause of disease.

There is another difficulty which makes it sometimes impossible to recognize reaction of degeneration, even when the muscles are totally paralyzed from peripheral lesion. This is the greatly diminished muscular excitability, even to the galvanic current, in the late stages of the reaction of degeneration. Frequently the batteries are either too weak to excite contractions, or so strong a current is required that either the pain or the electrolytic action of the current upon the skin prevents the examination. Such an exceptionally diminished irritability should be considered for clinical purposes as practically equivalent to the reaction of degeneration. (See p. 1029, *Direct Injury to the Muscles by the Toxins*.)

We can sometimes utilize an electric examination to locate some obstruction to conduction in a peripheral nerve (Fig. 398). If some obstruction to the conduction, *i. e.*, some injury, occur at *c*, no contraction will result from a stimulation between *a* and *c*, but will from one between *c* and *b*. In this way the lesion can be localized at *c*, provided the nerve is accessible to examination throughout a considerable extent of its course. The test will fail, of course, if *c b* be no longer capable of being stimulated, *e. g.*, in a severe degenerative lesion where the nerve below *c* soon loses its irritability, and will be successful only in a comparatively fresh or mild paralysis in which there is at least a

partial reaction of degeneration. This condition is well illustrated by the so-called "drunkard's paralysis" or "sleep paralysis" of the musculospiral nerve, in which we can sometimes locate the injury at the point of origin of the radial nerve, because ordinarily the radial nerve can be stimulated directly above this point, *i. e.*, in the axilla, or, for the supinator longus, at Erb's point. (See note to Fig. 391.)

5. PROGNOSTIC SIGNIFICANCE OF THE ELECTRIC REACTION

Nothing could be more misleading than to base the prognosis upon the alteration in the electric reaction without at the same time heeding other facts, especially the anatomic diagnosis, *e. g.*, a rheumatic facial paralysis, even with a typical reaction of degeneration, frequently recovers; whereas a cerebral hemiplegia with perfectly normal electric reaction is often incurable. Again, a myopathic muscular atrophy with normal electric reaction is no less incurable than a spinal muscular atrophy with reaction of degeneration. Many similar instances could be mentioned.

At the same time electrodiagnosis is often of incalculable value in determining the prognosis, provided that we limit the comparison of the electric examinations to cases of the same type, and draw our conclusions only after several careful examinations repeated at considerable intervals of time. A few examples will make this evident.

Rheumatic facial paralysis, which Erb has studied so carefully in regard to the sequence of its electric reactions, supplies us with an excellent example of the prognostic value of the electric examination. If in this disease reaction of degeneration can still be demonstrated after about fourteen days, it is evident, from the diagram upon p. 1024, that at least some months, or under some conditions even as much as a year, will elapse before perfect recovery will ensue, or the case may be incurable. If after the lapse of fourteen days no more pronounced alterations of the electric excitability occur, the paralysis is slight and may recover in a few weeks. If after the lapse of fourteen days only a partial reaction of degeneration occur, we can count upon recovery in eight to nine weeks (according to the scheme, Fig. 397). If the affection be severe and associated with reaction of degeneration, a single electric examination is not sufficient to determine whether it is curable or not. We must follow the entire course of the electric changes. If after the lapse of about thirty weeks we can determine no return of the motility and no improvement in the electric irritability, or perhaps a still further impairment, the prognosis would be very grave indeed (Fig. 396 c). Conversely, the slightest improvement in the electric reaction, *viz.*, an increase of the galvanic irritability in the nerve or the muscle supplied by it, or even cessation of its further depression, is of favorable significance.

The above-mentioned prognostic laws apply only to those peripheral paralyses which, like a rheumatic facial paralysis, owe their existence to a single injury, *i. e.*, whose anatomic causes neither persist nor progress. It would be obviously illogical to apply this law to other types of facial paralysis, such as a paralysis caused by a tumor or by an osteitis of the petrous bone, or even to the facial paralysis of a bulbar palsy. The distinction is that the rheumatic facial paralysis tends to recover, whereas these others tend to persist and progress.

The prognosis in a case of *infantile spinal paralysis* (poliomyelitis

acuta) is also very materially assisted by the results of an electric examination. For, just as in rheumatic facial paralysis, the cause is in operation but a short time; even in the very severe cases of poliomyelitis the cause persists and progresses for only a few weeks, and after that the disease itself is stationary. If after fourteen days to three weeks no reaction of degeneration can be detected in certain of the affected muscles, we can safely apply the same prognostic law to them that we have just mentioned for a rheumatic facial palsy. Reaction of degeneration is, however, a much more serious sign in poliomyelitis than it is in a rheumatic facial palsy, for experience has taught us that in infantile paralysis those muscles which show reaction of degeneration never recover. The reason is probably that the lesion is located in the central organs, which have little or no recuperative power.

With *lead palsy* reaction of degeneration almost always appears promptly, or, at least, a pronounced diminution of the muscular irritability to the galvanic current (see pp. 1029 and 1031) promptly results; either effect is equally significant from the prognostic standpoint. If no pronounced decrease in the electric excitability occur some time after the onset of a lead palsy, the prognosis will be favorable, just as in the rheumatic facial palsies. In lead paralysis, however, there is nothing absolutely unfavorable in the appearance of reaction of degeneration or in the pronounced diminution of electric irritability mentioned above. Only examinations repeated at considerable intervals suffice to determine the prognosis in cases of lead paralysis with reaction of degeneration. If the reaction constantly progress, the prognosis is grave; if, on the contrary, it remain the same, the prognosis is less serious; and if it evidently improve, the prognosis is favorable; for experience has taught us that when once an improvement commences in a lead paralysis, it almost always proceeds to complete recovery, and that partial recoveries are much less common. The same is found in polyneuritic and diphtheric paralyses.

We scarcely need mention that in polyneuritis there is a very decided tendency to recover just as soon as the determining causes stop; and, of course, this fact, as well as the result of electric examination, must be kept in mind in making the prognosis, which must always be determined separately for each individual muscle, and not for all those affected.

In central paralyses due to lesions in the supranuclear neurons, the results of electric examination are of less prognostic significance than in disturbances due to lesions of the peripheral neurons. For the electric irritability is not, as a rule, very much altered in these cases, even when the prognosis has from the onset been grave. However, an unfavorable prognosis should be given in disease dependent upon central lesions (cerebral hemiplegias, transverse lesions of the cord) which lead to a pronounced depression of the electric irritability, because they point to a decided secondary involvement of the peripheral motor neurons. This ill effect may be combated up to a certain point by appropriate electric treatment.

THE DEMONSTRATION OF ELECTROMOTOR EFFECTS IN THE HUMAN BODY

There are many interesting physiologic observations on the manifestations of the electromotor force in the organism during the performance of its functions. Probably the best known are the negative current vibrations set up in an

irritated nerve. Some of these may be demonstrated on the living human body, especially the currents flowing synchronously with cardiac activity (Waller), and also those currents which may be produced by muscular contractions, although these are probably due to a stimulation of the secretion of the cutaneous glands, rather than to muscular action itself. More recently, attempts have been made to employ the electric phenomenon of the cardiac activity as a physiologic and clinical method of examination in the form of an electric cardiograph, but the instruments necessary for this kind of an examination are so complicated and the examination itself is so delicate and tedious that it has so far received no general recognition. The so-called psychogalvanic reflex phenomenon has a better outlook for practical use. This phenomenon was first studied by Ferée, Tarchanow, Sticker, and Sommer, but latterly has been more carefully investigated and described by Veraguth. It consists essentially of two manifestations: If two electrodes be placed upon two areas on the body surface and a weak galvanic current, whose strength is measured by a very sensitive coil galvanometer be passed through the body, the strength of the current is found to sink at the moment when the individual receives a sensory stimulation, either because of increased resistance or because of the generation of a new opposing electromotor force, sufficient to be recorded in a galvanometer. Secondly, if the electrodes be applied to the skin without current, there appears at the time of the sensory stimulation enough current to cause a movement of the galvanometer. The psychogalvanic reflex shows a latent period of several seconds. Veraguth concludes from this that it is not really the effect of an altered contact in consequence of a reflex movement of the individual. He believes that it is probably connected with the function of the skin-glands, since he found that local poisoning of the cutaneous glands with atropin interferes with the phenomenon. This explanation agrees with the theory of physiologists, that cutaneous currents are set free by the activity of the skin-glands. (See Tigerstedt, *Lehrbuch der Physiologie*, 1905.) Veraguth has found that the psychogalvanic reflex phenomenon is dependent upon the intensity of the effect of the sensory stimulation. For example, an auditory impression without much effect, *i. e.* an unimportant sentence spoken to the individual, does not affect the galvanometer; on the other hand, sounds which possess a pleasant or an unpleasant effect upon the individual do. The psychogalvanic reflex phenomenon will probably attain a practical value by enabling us to control disturbances of sensibility objectively. Veraguth found that an irritation of certain cutaneous areas which are anesthetic because of a lesion of peripheral sensory nerves produces no psychogalvanic reflex, but that in hysteric anesthetics, irritation of the anesthetic parts causes this reflex to appear. This fact is all the more remarkable because the perception of the sensory irritation which is otherwise decisive for the intensity of the phenomenon is lacking in hysteric sensory disturbances, as well as in a peripheral disturbance of sensibility. The practical application of these experiments demands certain special precautionary measures which cannot be discussed here.

B. SPECIAL PART

I. EXAMINATION OF THE DIFFERENT CRANIAL NERVES

In examining the cranial nerves, the most convenient and logical plan is to take them up one after the other in their anatomic sequence. In the case of the nerves to the ocular muscles, it is, however, more practical to examine them all together, beginning with the third pair—the oculomotor.

FIRST CRANIAL NERVE; OLFACTORY

To test this nerve we employ substances with different odors, such as cologne, asafetida, oil of anise. We request the patient to smell each of them, closing first one nostril and then the other. It is convenient to test the trigeminus at the same time, employing for this purpose acetic acid and ammonia. The two sides should be tested separately. If any differences be observed, we must not attribute them to the olfactory or the trigeminus until we have convinced ourselves by a careful rhinoscopic examination that they do not depend

upon a local alteration of the mucous membrane. Disturbances of smell are very frequently due to a unilateral or bilateral inflammatory swelling of the nasal mucosa, which either injures the olfactory nerve-endings or interferes with the entrance of the odorous vapors by narrowing the nasal cavity.

Among other conditions, cerebral pressure may generally produce a paralysis of the olfactory, and, according to Huguenin, have the same significance as choked disk. A unilateral diminution of smell, provided no local cause exists in the nasal mucous membrane, appears most frequently as an accompaniment of the *hemianesthesias of hysteria* and of the *traumatic neuroses*. It is purely functional. The so-called *capsular hemianesthesia*, which depends upon lesions of the posterior part of the internal capsule, is not ordinarily associated with any disturbance of smell. (See p. 1090.) The olfactometer, constructed for physiologic examinations, has very little clinical utility, because only the gross changes, easily demonstrated without any instrument, are of any diagnostic importance.

SECOND CRANIAL NERVE; OPTIC

1. Determination of Acuity of Central Vision.—Snellen's, Pflüger's, or Steiger's well-known test-types are the most convenient and suitable for testing the acuity of central vision. Landolt's new vision tests are more conveniently carried about, and therefore better adapted for examining patients in bed. Errors of refraction must first be corrected. Ophthalmologic text-books must be consulted for more exact directions. We should remember, however, that even if the acuity of vision be normal, we cannot absolutely conclude the existence of pronounced changes of the retina or of the optic nerve, so that an ophthalmoscopic examination is essential (retinal hemorrhages, retinitis, choked disk, optic atrophy).

2. Testing the Field of Vision.—We employ the *perimeter* (Fig. 399) to determine accurately the field of vision; to demonstrate hemiopia and other visual defects (as central scotomata, quadrant defects, and quadrant anopsia); to establish the existence of unilateral or bilateral limitations of the visual field, such as accompany hysteria and other neuroses, especially the so-called traumatic neuroses, as well as to show the frequently associated fatigue of the retina. Books upon ophthalmology must be consulted for the technical application of this instrument.

We can determine the visual field approximately by a very simple procedure. The patient, with his left eye closed, sits opposite the examiner. The latter closes his right eye. The patient's right eye and the examiner's left eye are now fixed upon each other; the examiner then moves his finger in a frontal plane midway between the two eyes, from the periphery into the field of vision. He can then directly compare the patient's field of vision with his own. Of course, the distance of the finger from each eye should be exactly alike. With but one eye, it is difficult to be accurate about this distance, so that it is advisable for the examiner to orient himself by opening the closed eye from time to time. Pronounced defects in the visual field are, according to the author's experience, easily recognized by this method.

Significance of Scotomata or Defects in the Visual Field.—Dufour was the first to call attention to the great difference between "not seeing"

(vision nulle) and "seeing indistinctly" (vision obscure). If the visual defect consists of a simple lack of perception (not seeing), without obscuration of the affected areas in the visual field, the trouble must be attributed to a functional or anatomic lesion of the visual center in the cortex. Very likely the patient appreciates it for the first time during the examination. Should the patient, on the contrary, complain that the defect in the visual field does not appear to be complete,

Fig. 399.—Perimeter. The examination may be made with the carrier which moves along the semicircle, or the test objects may be carried along this by means of dark disks attached to a long handle, each disk containing in its center the test object. The patient's chin is placed in the curved chin rest; the notched end of the upright bar is brought in contact with the face, directly beneath the eye to be examined, which attentively fixes upon the center of the semicircle. The other eye should be covered, preferably with a neatly adjusted bandage. The record chart is inserted at the back of the instrument, and, by means of an ivory vernier, the examiner is enabled to mark exactly with a pencil the point on the chart corresponding to the position on the semicircle at which the patient sees the test object. The various marks are then joined by a continuous line.

but merely an obscured area (in which case the patient is annoyed by this condition and is conscious of it), we should then naturally conclude that the visual center is intact, and that the visual defect depends upon some involvement of the visual conducting apparatus, either of the refracting media, the retina, the optic nerve, the optic tract, or the visual fibers. "Seeing indistinctly" is nothing more than the reaction of the intact visual centers to a faulty transmission of optical impulses; whereas "not seeing" is a consequence of the lack of visual perception of the

object in question, and naturally it occurs only in functional disturbances or anatomic lesions of the visual center. This distinction between "not seeing" and "seeing indistinctly" is of special importance in the differential diagnosis between *central* and *peripheral hemiopia*. Thus, the observation that the hemiopic scotoma in scintillating scotoma or in ophthalmic migraine is an absolute defect and not an obscuration of the visual field entirely agrees with the supposition (probable from other reasons) that the process is central and located in the cortex. (See p. 981.)

Fig. 400.—Diagram of the course of the optic fibers.

Visual Color Fields.—We are often assisted in the diagnosis of hysteric and other neurotic conditions by determining the visual color fields. These are frequently contracted and their sequence disturbed. The visual field for blue is normally the largest; but in the above affections we frequently find that other colors overlap its borders. The text-books upon eye diseases show how to determine these conditions by means of the perimeter.

Compare section 4 for the topographic diagnostic significance of defects in the field of vision.

3. **Ophthalmoscopic Examination** (see p. 907 et seq.).

4. **Topographic Diagnosis of Lesions in the Course of the Optic Fibers.**—Fig. 400 represents diagrammatically the course of

the optic fibers from the retina to the occipital lobes. The fibers arising from homonymous retinal halves form the optic tract by a semi-decussation at the chiasm. Then they proceed, in part directly, but mostly indirectly, through the so-called primary optic centers to the occipital cortex.

Without further explanation, the diagram (Fig. 400) makes it plain that a focal lesion (*a*) of the optic nerve will cause unilateral blindness; a lesion (*b* or *c*) in front or behind the chiasm will cut off the nasal halves of the retina and produce a temporal hemiopia; a lesion at *d*, *e*, or *f* will cut off both left-sided retinal halves and produce a homonymous right-sided hemiopia.

It is characteristic of the defects of the visual fields in hemiopia that the point of fixation¹ and its immediate vicinity are represented in both optic tracts, and therefore in both hemispheres, by the overlapping of fibers on the boundaries of

Fig. 401.—Grasset's modification of the preceding diagram: The optic fibers are depicted for simplicity sake, as if they were uninterrupted, without intercalation of the primary optic centers.

both halves of the visual fields. Consequently, in the clinical picture of hemiopia the acuity of central vision need not necessarily be impaired. In fact, the disturbance may be so slight that it is detected only by special examination; because the patient can easily displace the object images from the blind to the good half of the visual field by means of appropriate ocular movements.

Grasset has modified Fig. 400 hypothetically in Fig. 401 in order to explain the occurrence of unilateral blindness from a lesion in the extreme posterior (sensory)

¹See Wernicke, *Lehrbuch der Gehirnkrankheiten*, 1881, vol. i, p. 234; *ibid.*, *Deut. Klinik*, 1906, vol. vi, No. 1, *Der aphasische Symptomen-complex*, p. 519.

portion of the internal capsule. This condition is sometimes observed instead of a hemiopia. For the sake of simplicity the optic fibers are represented in this diagram as uninterrupted, i. e., the primary optic centers are omitted. In this diagram it is assumed that the fibers which have not already crossed at the chiasm decussate between the corpora quadrigemina and then return directly to their original side; both *a* and *b* are supposed to be situated in the posterior part of the internal capsule. Hence a lesion in the internal capsule will, according to its position, produce either a crossed blindness, i. e., *amblyopia* (lesion *a*) or a *homonymous hemiopia* (lesion *b*). Recent observations, however, seem to prove that lesions of the internal capsule probably do not produce hemiopic disturbances of sight. Henschen has recently examined the innervation of the different retinal quadrants, i. e., the course of the visual fibers of each retinal quadrant in the trunk of the optic nerve and in the optic tracts. By dividing the retina into four quadrants by a vertical and a horizontal meridian, he found that the visual fibers of each of these quadrants run as a compact bundle in the optic fibers. This circumstance can sometimes be utilized in establishing, by aid of an exact representation of the visual field, a local diagnosis of peripheral interruptions of the visual fibers (optic atrophy, tumors).

The following diagrams from Henschen¹ illustrate this point:

5. Detection of Simulated Unilateral Blindness.—Unilateral blindness is quite frequently simulated. Ordinarily, we can discover it very readily by using the stereoscope. The instrument is placed in

Fig. 402.—I. The four retinal quadrants: To the left is the position in cross-section of the fiber in the vascular part (anterior) of the optic nerve. The shaded parts correspond to the macula lutea, i. e., the transmission of central vision. The arrows show the way the retinal quadrants correspond to the individual parts of the optic nerve. This arrangement of the fibers can be similarly made out at the part of the optic nerve which is visible to the ophthalmoscopic (optic disk) examination. *incr*, Retinal quadratus with uncrossed fibers.

II. Cross-section of the optic nerve in the non-vascular (posterior) portion. Here the macular bundles (represented by shading) lie in the center of the nerve, and the fibers corresponding to the individual retinal quadrants are arranged in quadrants about an imaginary axis running in the center of the nerve.

Explanation of the terms in the figure: The fasciculus dorsalis cruciatus corresponds to the internal superior retinal quadrant. The fasciculus ventralis cruciatus corresponds to the internal inferior retinal quadrant. The fasciculus dorsalis incruciatus corresponds to the external superior retinal quadrant. The fasciculus ventralis incruciatus corresponds to the external inferior retinal quadrant.

The figure also shows that the quadrant arrangement is retained in the non-vascular part of the optic nerve, i. e., by imagining the quadrant picture of the retina seen from in front (I) with the upper end of the vertical meridian rotated outward about 45°.

III. Cross-section of the posterior part of the optic tract: *P. F.*, Fibers of the pupillary reflex (see Fig. 413, p. 1054). Other abbreviations have the same meaning as in II. The four quadrant bundles are bound together again, but still distinct. They surround the shaded bundle in the center, which corresponds to the tract of the macular fibers. The arrangement of the quadrant bundles in III. is very similar to that in the cross-section II., except that the pupillary fibers do not appear in the latter.

front of the two eyes; different letters are arranged so as not to coincide in stereoscopic union. The patient cannot recognize to which eye the individual pictures belong. If, now, he simulate a one-sided blindness, the simulation is evident, because he reads the characters which could be seen only by the supposedly blind eye quite as well as the other.

This outcome of the test does not, however, prove malingering in hysteria, because there are cases of unilateral hysteric blindness in

¹ See Salomonsohn, Deut. med. Woch., 1900, No. xlii, p. 677.

which the disturbance is shown solely during monocular vision. For the test to be free from objections, due care must be exercised that the patient obtains no information by alternate opening and closing of a single eye or by moving the picture. Appropriate stereoscopic pictures for such an examination with the stereoscope will be found at the end of Dr. M. Burchardt's treatise, "Practical Diagnosis of Simulation" (Berlin, Enslin, 1891).

THIRD, FOURTH, SIXTH CRANIAL NERVES; THE OCULAR MUSCLES; NERVES, INCLUDING THE SYMPATHETIC MOTOR INNERVATION OF THE EYE REGION

1. Functions of the External Ocular Muscles

The *third cranial nerve* (oculomotor) supplies the following muscles: Levator palpebræ superior, rectus superior, rectus inferior, rectus internus, and obliquus inferior, the pupillary sphincter, and the muscles of accommodation (both the latter from the short branch of the ciliary ganglion).

The *fourth cranial nerve* (trochlear) supplies the superior oblique (trochlearis) muscle.

The *sixth cranial nerve* (abducens) supplies the external rectus muscle.

The muscles which move the eyeball have the following functions:

I. Internal rectus: movement of the eyes inward without any meridian inclination.

II. External rectus: movement outward without meridian inclination.

III. Superior rectus: movement upward and inward with rotation of the upper extremity of the vertical meridian inward.

IV. Inferior oblique: movement upward and outward with rotation of the upper extremity of the vertical meridian outward.

V. Inferior rectus: movement downward and inward with rotation of the upper extremity of the vertical meridian outward.

VI. Superior oblique: movement downward and outward with rotation of the upper extremity of the vertical meridian inward.

The external and internal recti suffice for directing the eyes in the horizontal axis, but movement in the vertical axis (upward and downward) requires the joint action of one rectus and one oblique. The inferior oblique belongs to the superior rectus and the superior oblique to the inferior rectus. The principal function of the obliques is, therefore, to limit the tendency to inward movements and to rotation of the eye in the frontal plane, which would take place without their action. Any vision directed obliquely between the vertical and the horizontal axes necessitates the joint action of three different muscles. One of them acts to prevent rotation in a frontal plane.

2. Paralysis of the Muscles which Move the Eyeball

The disturbance of function which may result from a paralysis of the eye muscles can be essentially determined from the preceding description of their function. If one or more muscles of the eye be paralyzed, the eye will remain immobile when an attempt is made to turn it in the direction ordinarily accomplished by the muscles affected. To demonstrate the existence of a paralysis of the eye muscles, the patient should follow with his eyes (but with the head absolutely

fixed) the movement of the examiner's finger in every direction, while the examiner compares the excursions of the two eyes. This is easily accomplished by observing the position of the corneal margin in relation to the angle of the eye, a procedure generally sufficient for a hasty test. A slight paresis may, however, be hidden by the tendency such a patient has to fuse the double images. Therefore, in any doubtful case, it is well to test each eye alone, covering the other eye. A slight weakness will sometimes be disclosed by having the patient attempt the extreme positions, and then observing either that the position cannot be retained for any length of time or, else that it produces an accompanying tremor of the globe (nystagmus, see p. 1050), although the weakness is not sufficient to diminish the extent of the excursions. In testing the internal recti we must especially note their behavior in attempted convergence of the eye. (See p. 1049.)

In complicated muscular paralyses of the eyes it is often difficult to form a judgment as to the function of the oblique muscles, because they are in such intimate association with the recti. In such a case, and especially in distinguishing the more delicate disturbance of the eye movements, testing the torsion of the eyeball is especially significant. If the eyeball move normally, no axial deviations occur, because the tendency to such deviations common to all the eye muscles, excepting the external and internal recti (p. 1037), is counteracted by the associated action of the other muscles. Just as soon as this extremely finely balanced associated action of the eye muscles is injured by the paralysis of such muscles as possess axial deviating components, axial deviations of the eyeball must ensue. The demonstration of such axial deviations or movements of rotation in a definite visual direction, and the determination of the muscles which are responsible, permits conclusions in regard to the finer defects of movement. These cannot be made out in an examination of the gross excursions of the eyeballs, for in complicated paralyses it is especially difficult to recognize the functions of the obliques in the movements of the eyeball, because the direction in which these muscles pull is affected by the action of the two recti muscles. In order to draw diagnostic conclusions concerning rotation it is only necessary to keep in mind that rotation with an inclination of the upper extremity of the vertical meridian inward depends upon the superior rectus and the superior oblique, while the reverse rotation depends upon the inferior rectus and the inferior oblique. If a rotation occur in any individual movement of the eye, we naturally infer that the fault depends upon the muscle, which by its help should prevent such rotation, and which, unaided and unopposed, would accomplish the opposite rotation. We test rotation by having the patient look upward and outward, and then downward and outward.¹ While looking upward and outward, rotation of the right eye in the direction of the hands of a clock (as seen by the examiner) signifies paresis of the inferior oblique and preservation of the superior rectus; while looking downward and outward, a similar rotation signifies paresis of the inferior rectus with intact superior oblique.

More pronounced paralyses of the eye muscles are also evidenced by strabismus (*paralytic squinting, paralytic strabismus*). Paralytic strabismus can be differentiated from concomitant strabismus by the fact that in the former a deviation of the eyeball from the normal reciprocal

¹ Or if these movements cannot be carried out, having him make the attempt.

position shifts with the direction of vision, whereas in concomitant strabismus it remains the same in every direction of vision.

Patients with paralysis of the eye muscles ordinarily complain of double vision; hence the existence of diplopia and its peculiarities may be utilized for diagnosis. For this purpose it is essential to know to which eye each one of the double pictures belongs. This is determined most readily by putting before the patient's eyes differently colored glasses, which may be conveniently slipped into the spectacle frame used by ophthalmologists. From the patient's statements as to the color of the pictures it is easy to determine the eye to which each of the double pictures belongs. In some cases, especially in old paralyses, double vision is first discovered by making use of these colored glasses, whereas without this device patients disregard one of the pictures, *i. e.*, they no longer see it. It is quite possible, without the colored glasses, to determine to which eye each of the double pictures belongs, by covering one of the patient's eyes, and then having him say which of the pictures disappears. In paralyses of the eye muscles which act horizontally, the double pictures will stand side by side. These we call *crossed double pictures* (*crossed double vision*), if the picture lying to the left (from the patient) belong to the right eye. On the contrary, we speak of *homonymous* or *non-crossed double pictures*, if the left picture belong to the left eye. In accordance with well-known physiologic laws of projection, the appreciated picture—that is, the projection of the retinal picture in space—seems to be inverted. Hence *homonymous* or *non-crossed double pictures* depend upon a crossing of the visual axis in front of the object, *i. e.*, upon convergence; or, in other words, upon abducens paralysis. On the contrary, *non-homonymous* or *crossed double pictures* depend upon divergence of the visual axes, *i. e.*, paralysis of one or both internal recti. The following laws of double vision are applicable for diagnostic use. They depend upon the fact that the projection of the retinal pictures in space seems to shift in a direction opposite to the movements of the eye.

(1) That eye is paralyzed whose image appears to be deviated from that of the other in any one direction of vision; and (2) the paralysis involves the muscle or muscles which move the eyeball in the same direction in which the deviated object seems to shift when the line of vision is altered.

In examining for double vision it is useful to know that some cases see double only when objects are at a considerable distance from the eye; perhaps because the effort of accommodation in focusing at a near distance makes it easier to disregard the second indefinite picture. It is also important to remember that double pictures separated but little from one another are frequently not recognized as such by the patient, but are described by him as "blurred" (*i. e.*, obscure) vision. Closing one eye improves the patient's vision in this type of disturbance.

Besides double vision, patients with paralysis of the eye muscles very frequently complain of *vertigo* (ocular vertigo), and *disturbance of equilibrium* in walking and standing. (See pp. 1093 and 961.) This is psychic and depends upon the disturbances of orientation in space. According to the author's experience, ocular vertigo depends principally upon paralysis of the ocular muscles which rotate the eyeballs; whereas mere paralysis of the abducens and internal recti ordinarily causes little or no vertigo. This is comprehensible without further explanation; for, despite the diplopia, the patient with these latter paralyses sees objects at least in normal vertical orientation; whereas in paralysis leading to rotation, objects appear upside down.

Fig. 403.—Diagram of the bilateral central innervation of the nerves to the eye muscles and most of the remaining motor cranial nerves. The lesion *x* causes no evident paralysis, because the tracts of the opposite side remain intact; the lesion *y* would, however, and so would lesions *x* and *z* together. Coexisting lesions in the latter places (*x* and *z*) cause so-called bulbar paralysis (p. 1090).

Ocular vertigo differs from other kinds of vertigo, inasmuch as it disappears upon closing the eyes.

If the paralysis be simple, and especially if it be unilateral, the diagnostic laws concerning the significance of the kind of double pictures mentioned above easily lead to a diagnosis; but in complicated binocular paralysis the recognition of the paralyzed muscles from the double pictures alone is often very difficult. Here one of the most reliable methods is to determine the fields of vision by means of the *perimeter*. It is merely an improved method of testing the excursions of the eyeball in various directions, and is accomplished by fixing the head by means

Fig. 404.—Unilateral ptosis (New York City Hospital).

of the perimeter, and estimating those points in the instrument which can be directly (centrally) seen, *i. e.*, at which fine type can still be read. The projection fields may be recorded on charts just as the visual fields.

Monocular double vision, which is not uncommon in hysteria, must not be confused with binocular diplopia occasioned by paralysis of the muscles of the eye. The former is often attributed to a partial spasm of the ciliary muscle, in consequence of which a portion of the lens acts as a prism and throws a second picture upon the retina. This theory is probably incorrect, for certainly it will not apply to many cases; in those which the author himself has observed the monocular diplopia was evidently a purely psychic phenomenon. Monocular diplopia is, therefore, a *stigma*

of hysteria, and it is important to bear this in mind in any instance of double vision, before making a diagnosis of ocular muscle paralysis, which causes only binocular diplopia.

The diagnostic importance of ocular muscle paralysis is very considerable, because experience has shown that it almost always depends upon a lesion of the peripheral motor neurons (*i. e.*, the subnuclear fibers or the nuclear region itself) and practically never upon a supranuclear lesion, or a lesion of the central fibers. As each one of the ocular nerve-muscles must possess a central tract running to the cortex, this peculiarity demands explanation. This may be given by the supposition that the nuclei of the ocular muscles are innervated not by one, but by both hemispheres. Fig. 403 readily explains why a lesion in one hemisphere, even if it destroy the central fibers, causes no apparent paralysis of the corresponding eye muscle, although a portion of

Fig. 405.—Bilateral ptosis, normal position (Neurologic Department, Massachusetts General Hospital).

the innervation for both sides is affected, the intact hemisphere apparently furnishes sufficient innervation for both sides. Therefore, since there is no method of measuring the absolute power of the muscles, the bilateral defect of innervation escapes observation. This is also difficult in the case of the other cranial nerves where analogous conditions exist. When the lesion, even though small, occurs at *y*, in the region of the nucleus or below it, all the fibers are interrupted. Still another circumstance may aid in preventing the occurrence of a muscle paralysis in unilateral supranuclear lesions of the hemisphere; it is possible that the central fibers do not run so compactly as is represented in the figure, but are distributed over different points of the cortex, so that a circumscribed lesion could not very easily destroy many of them. In favor of this is the fact that Beevor and Horsley, in their experiments on the internal capsule of apes were able to cause conjugate lateral movements

of both eyes (rectus internus and contralateral rectus externus) only. (See Fig. 427, p. 1097, irritation points of the internal capsule.)

Fig. 406.—Bilateral ptosis, showing effort to open eye, using muscle of forehead (Neurologic Department, Massachusetts General Hospital).

On the other hand, in bilateral hemispheric lesions or in excessive superficial affections of the two sides of the brain (meningitis, etc.), bilateral ocular muscle

Fig. 407.—Bilateral p

(General Hospital).

Massachusetts

paralyses may occur as "pseudobulbar" paralyses (p. 1090). The few examples in which, with unilateral cortical lesions, contrary to ordinary experience, isolated

crossed ocular muscle paralyses (especially ptosis) have been discovered are explained by assuming that in many individuals the bilateral hemispheric innervation is insufficiently developed, or that the central fibers are more compact and localized. In one of these cases that part of the frontal lobe adjacent to the middle portion of the anterior central convolution was found to be involved, and in the other cases the parietal lobe. The first corresponds to localization of the center for conjugate ocular movements. (See p. 1046, Fig. 424, p. 1095.) The latter is probably due to a lesion of the association fibers connecting the center for optic perception with the center for ocular movements (see p. 1046); this causes a disturbance of ocular motility because of the loss of physiologic innervation. Isolated ptosis of central origin has been found only in lesions of the parietal lobe. This will be discussed upon p. 1046 along with the localization of the center for conjugate ocular movements. (See Fig. 424, p. 1095.)

In paralyses of the ocular muscles one can, therefore, generally exclude supranuclear causes, so that a diagnosis of the situation of the lesion is for the most part limited to a distinction between a nuclear and a subnuclear type. This differentiation in the case of the oculomotor is frequently simple, because in subnuclear (*i. e.*, entirely peripheral) paralysis the nerve is affected almost always in toto, whereas in nuclear paralyses the separate functions of the nerve can be affected, so to speak, individually, since the oculomotor nucleus is anatomically situated in functionally different areas. Especially characteristic for most nuclear paralyses is the preservation of the pupillary and accommodation fibers of the oculomotor. The following plan, copied from Kahler and Pick, presents the anatomic arrangement of the different parts of the oculomotor nucleus and their relation to the neighboring trochlear nuclei. Its study will facilitate a more exact local diagnosis in nuclear paralyses.

Anatomic Arrangement of the Different Components of the Oculomotor Nucleus.

			[Anterior (proximal).]	
			1. Accommodation.	
			2. Sphincter iridis.	
Median.	{	3. Rectus internus.	5. Levator palpebræ superioris.	} Lateral.
			6. Rectus superior.	
		4. Rectus inferior.	7. Obliquus inferior.	
			Trochlearis.	
			[Posterior (distal).]	

3. Ptosis, Including So-called Sympathetic Ptosis

By ptosis is meant a paralytic drooping of the upper eyelid so that the lid covers the eyeball more or less completely and thereby narrows the palpebral fissure. Ptosis ordinarily results from paralysis of the levator palpebræ superioris, supplied by the oculomotor. (See below, Sympathetic Ptosis.) In this connection it is necessary to differentiate paralytic ptosis from a spasmodic condition of the orbicularis palpebrarum, by which the upper lid is drawn down over the eye and the palpebral fissure narrowed. The distinction is usually easy. In the former, paralytic or true ptosis, the excursion of the upper lid upward, is diminished if not entirely prevented; whereas in a spasm of the orbicularis this need not be the case, because unless the spasm be too strong, the levator is able to overcome the tonus of the orbicularis. In a spasm of the orbicularis, moreover, the wrinkles about the eye are ordinarily more prominent, and the eyebrow is placed lower than upon the normal side; whereas in paralytic ptosis the eyebrow, by means of its innervation

by the facial, seems instinctively elevated higher than normal to counter-balance the defect.

The so-called *sympathetic ptosis*, which was first described by Horner in 1869, must not be confused with ptosis due to paralysis of the levator palpebræ. Here, although the lid aperture of the affected side is narrower than upon the healthy side, and its upper lid hangs lower, it can be demonstrated that the excursions of the levator palpebræ are in no way diminished; but the eyeball often seems sunken into the orbital cavity, the pupil is ordinarily somewhat narrowed, and frequently abnormalities of the sweat secretion and of the vascular innervation appear upon the affected side of the face. This symptom-complex depends upon a paralysis of the so-called Müller muscle (supplied by the sympathetic), comprising the smooth muscle-fibers of the superior oblique, inferior oblique, and orbitalis. Stimulation of the two former widens the lid aperture; stimulation of the latter projects the eyeball somewhat forward from the orbit. A paralysis of these fibers causes an appearance of the eyes diametrically opposite to that in Graves' disease (exophthalmos) (Gräfe's symptoms, see p. 1050). This latter symptom is to be attributed to an irritation of these smooth muscles.

Congenital ptosis, which is not very rare, is partly sympathetic in nature, and partly dependent upon a congenital (nuclear) paralysis of the levator palpebræ superioris. Concerning isolated ptosis in lesions of the parietal lobe see p. 1045.

4. Conjugate Paralysis and Conjugate Deviation of the Eyes

The so-called conjugate eye paralysis will be discovered in a binocular examination for the mobility of the eyes (described above) by means of fixation upon the finger held in front. It occurs in cerebral diseases, and

Fig. 408.—Diagram of the tract for the associated lateral movements of the eyes. The upper half of the diagram, as far as the decussation (at upper edge of the pons), is to be regarded as a frontal section; the lower half of the diagram (the pons), as a horizontal section through the brain. The heavier of the two pairs of lines which intersect each other represents the central tract of the abducens; the lighter, the central tract of the internal rectus of the opposite side.

consists of weak, deficient, or absent mobility of the two eyes to the same side. These conjugate paralyzes are usually due to a lesion situated in a tract which apparently runs from the middle portion of the frontal lobe, adjacent to the anterior central convolution, to the nucleus

of the abducens of the opposite side and to the nucleus of the rectus internus of the same side. The cortical center of this tract lies, together with the center for the rotation of the head to the opposite side, in the foot of the middle frontal convolution,¹ i. e., the area bordering on the central convolutions. They may probably also be due to a lesion in a fasciculus which is situated in the infraparietal lobe and connects the center for ocular movement with the center of the optic nerve (Landouzy and Wernicke). A conjugate paralysis of the lateral ocular movements due to a lesion of this area may be reconciled with the theory that the real motor center for the movements lies in the frontal lobe (see above) if we assume that, in consequence of the close association of the visual sphere of one hemisphere with the ocular movements toward the opposite side, one that is quite inseparable from the usual visual act, a second innervation comes from the visual area during voluntary lateral projection. A paresis of the conjugate lateral ocular

Fig. 409.—The same diagram simplified.

movements starting from this point of connection may cause the loss of this second innervation current. Fig. 408 is a schematic representation of the course of this tract based upon pathologic findings (Leichtenstern-Hunnius). It will be seen that the fibers for the rectus internus, instead of passing directly to this nucleus, take a circuitous course through the region of the opposite abducens nucleus, and that the entire tract decussates in the anterior half of the pons.

In order to explain the way in which this tract can be affected by cerebral lesions at different locations, it is best to simplify the diagram, as in Fig. 409. The arrows mean that the tract proceeding from the cortex of the left hemisphere supplies the lateral movements of the eyes to the right; the tract from the opposite side, those to the left. With

¹ See author's monograph, *Beitrag zur corticalen Localization der conjugierten Seitwärtsbewegungen der Augen und des Kopfes*, Deut. Arch. f. klin. Med., 1905, Bd. lxxxvi.

this explanation it is easy to understand that a lesion (x) above the pons will prevent the movements of the eyes to the side opposite the lesion, while, on the contrary, a lesion (y) below the upper edge of the pons will paralyze the movements of the eyes to the same side as the lesion.

Since conjugate paralyzes are ordinarily combined with a conjugate deviation of both eyes to the side of the non-paralyzed antagonists, with a lesion x (Fig. 409) an ocular deviation to the right will be noted, and with a lesion y , one to the left. Briefly, in lesions above the pons the patient looks toward his cerebral lesion; whereas in lesions of the pons and below the pons, he looks away from it.

Conjugate paralysis with deviation of the eyes occurs principally as a symptom of hemiplegia in acute cerebral lesions (hemorrhage, softening). Like hemiplegic paralyzes of the extremities, it is frequently an indirect focal symptom, depending upon lesions located at various points,

Fig. 410.—The same diagram modified to include the uncrossed vicarious innervation.

and generally soon disappears with the subsidence of the remote action. In some cases, however, the persistence of the hemiplegia proves that the entire unilateral voluntary tract is destroyed, and with it the accompanying conjugate ocular tract (see Fig. 427, p. 1097, irritation points of the internal capsule), running through the internal capsule, and yet the conjugate ocular paralysis gradually disappears. We are compelled to assume, therefore, that, although most of the tract decussates, there must exist in the other hemisphere an uncrossed tract, possessed of the same function, which in apoplexy is affected more or less strongly by the remote action, but which, after the subsidence of the apoplexy, can take the place of the affected crossed tract. The ocular movement toward the same and opposite sides as a result of stimulation of the internal capsule (see Fig. 427, p. 1097, experiments of Beever and Horsley on apes) furnish direct experimental proof of the theory

of bilateral innervation of the conjugate movements of the eyes. Fig. 409 must, therefore, be modified in accordance with this theory, as in Fig. 410. Naturally, it may also be inferred that the vicarious action of the healthy hemisphere can be improved by constant use.

Besides being due to paralysis, conjugate deviation of the eyes may result from spasmodic action. This cause may be assumed when we note the existence of similar spasms in other muscles upon the side of the deviation. The local diagnostic conclusions from the direction of the deviation are then naturally simply reversed.

5. Paralysis and Weakness of Converging Movements of the Eyes

Convergence of the eyeballs requisite for binocular vision of near objects is naturally affected or rendered impossible by paralysis of one or both internal recti. Peculiar conditions occur, however, in which the internal recti functionate normally

Fig. 411.—Exophthalmic goiter, showing exophthalmos and goiter (Dr. J. J. Putnam, Massachusetts General Hospital).

for all conjugate lateral movements of the eyes, but not for converging movements. Such observations have led to the assumption of a separate convergence center probably located in the pons. Its existence, however, is still problematic, because isolated convergence paralysis could quite as well depend upon the paralysis of a special tract supplying each internal rectus as upon the lesion of a center. A lesion of a central tract (*i. e.*, a supranuclear oculomotor and probably a bilateral convergence tract), different from the tract of the conjugate movements of the eyes (Fig. 408), would explain the peculiarity. The one thing which seems to be certain

(and this was confirmed by one of the author's autopsies upon a tumor of the pons) is that convergence can be paralyzed by a lesion of the pons, while the other movements (conjugate, see p. 1046 et seq.) of the internal recti remain intact. In this sense the symptoms can be utilized for local diagnosis.

In addition to the characteristic and complete paralysis, a mere weakness and insufficiency of convergence may be of considerable diagnostic importance in neurasthenic states and in exophthalmic goiter. In the latter this phenomenon is called *Möbius's symptom*. Insufficiency of convergence, which occurs also in myopia, is experienced subjectively by the appearance of the so-called asthenopic difficulties, by a sense of fatigue, by obscure and double vision when the eye is steadily accommodated for near objects, and, on the other hand, objectively confirmed by the exhibition of latent external strabismus for near vision. This latent external strabismus appears when the binocular focusing power fails, and can be demonstrated by fixing the glance upon a near object (*e. g.*, 25 cm. distant) and then suddenly covering one eye with the hand. With insufficient convergence the covered eye will noticeably deflect outward, since the effort for convergence has become unnecessary. Conversely, the patient may also fix a nearby object while one eye is screened and then suddenly uncovered. In this case the eye previously covered and deflected turns inward for the purpose of binocular fixation. In spite of such subjective and objective confirmation of insufficiency of convergence, the degree of convergence which is transitorily accomplished by vigorous voluntary impulse is in such cases oftentimes considerable, so that, according to the author's experience, the Landolt ophthalmodynamometer (which measures the convergence attainable by the maximum voluntary effort) does not suffice to demonstrate the insufficiency in exophthalmic goiter.

6. Nystagmus

In examination of the eyes one must always be on the lookout for nystagmus, by which is understood a rhythmic oscillation of the eyeball, especially marked when the eyes are in an extreme position. It is much more commonly a lateral than a vertical movement. It is generally an intention tremor. (See p. 951.) It is frequently associated with paralysis of the eye muscles (see p. 1039), and with many other affections of the eye and of the brain, most commonly, however, multiple sclerosis. The neurodiagnostic importance of nystagmus is limited, because it occurs in all sorts of ophthalmologic affections, especially in those which early in life cause markedly defective vision, *e. g.*, in corneal opacity, in cataract, either congenital or early acquired, in congenital iridochoroiditis and retinitis pigmentosa, in coloboma of the choroid and of the retina, and finally in albinism. [Often more than true nystagmus in these last-named conditions, we encounter irregular twitching movements of the eyeballs, to which the designation nystagmoid movements is given.—ED.]

7. Contractions of the Ocular Muscles

A contraction of certain of the external ocular muscles, evidenced by anomalous positions of the eyeball, plays a part of some importance in hysteria. These positions change so constantly that it is impossible to confuse them with paralysis or with concomitant strabismus; besides, in hysteria, as contrasted with the latter condition, a voluntary movement fails to alter to any considerable extent, if at all, the position of the deviated eye in relation to the palpebral fissure. The history will generally aid in any doubtful case. A differential diagnosis between spasm and paralysis might be difficult in some instances unless the presence of contracture in an adjoining muscle (facial spasm, blepharospasm) should decide the question.

(See p. 1049 in regard to conjugate deviation of both eyes due to spasm.)

The so-called "Gräfe's sign," which occurs in exophthalmic goiter, is probably to be regarded as a spasmodic contracture of the sympathetic superior oblique muscle (p. 1046). This sign gives the patient with exophthalmic goiter a very characteristic expression, and is of con-

siderable diagnostic importance. It is elicited by having the patient look down gradually; as the eyeball lowers it is noticed that the upper lid does not follow the movement of the eyeball, but either remains still or moves only slightly, thus exposing a more or less broad band of sclera between the cornea and the upper lid. [This sign is not limited to Grave's disease, but may be seen in other diseases. Barker and Hanes¹ have published a series of 33 cases of chronic nephritis, 16 of which showed marked exophthalmos with von Gräfe's sign. They believe it to be the result of irritation of the autonomic sympathetic fibers. This causes contraction of Landström's muscular cuff or opponens recti.—Ed.] For its demonstration it is important to avoid a dazzling light, because, apparently for protection, this seems to furnish sufficient stimulus to enable a patient to overcome the phenomenon. Gräfe's symptom may be easily simulated, in which case the action of the levator palpebræ superior preponderates over that of the smooth tarsal muscle.

8. The Pupillary Phenomena

Diagnostically, these are of the greatest importance.

Diameter of the Pupils.—The size of the pupils can only be estimated in regard to the illumination. It is best to observe them in illumination of medium intensity. In doubtful cases we should compare the pupils of the patient with those of a healthy man, of about the same age, in the same light.

Schirmer² found that the diameter of the pupil under physiologic conditions varies greatly in different individuals, and especially at different ages. In any individual case, however, the diameter is constant for wide ranges of illumination (from 100 to 1100 meter-candles), provided that the observation be made after the eye has fully adapted itself to the particular illumination, as it does within a few minutes. If we bear this fact in mind in estimating the diameter of the pupil, we are, to a certain extent, independent of the existing degree of illumination. This diameter of the pupil, determined several minutes after full adaptation, must consequently be employed as a basis for the recognition of pathologic variations. Schirmer obtains the necessary degree of illumination of 100 to 1100 meter-candles by placing the patient within one meter of a window which is well illuminated by the sun, and yet not exposed to direct sunlight. The pupillary diameter is then determined while the patient relaxes his accommodation and convergence by looking at some distant object. Schirmer states that the observation should not be made when passing clouds are present, since the illumination will vary and may be less than 100 meter-candles. Tange found by observing these conditions that the pupillary diameter varied between 2 and 4 mm., being dependent upon age, refraction, and sex, and that in the great majority of cases it was between 2.5 and 3 mm. In advanced life the pupil is usually smaller than in youth.

Narrowing of the pupil (miosis) is found physiologically during sleep and old age, pathologically as an early symptom in *tabes dorsalis* and in *progressive paralysis*. Eserin, pilocarpin, opium, morphin, and chloroform (the latter in pronounced narcosis) narrow the pupil. Sympathetic miosis from lesions of the (pupillary) dilating fibres of the cervical sympathetic, from disease or the sympathetic itself or of the oculopupillary fibers connecting the sympathetic nerve with the first dorsal segment of the spinal cord, is of local diagnostic importance.

Dilatation of the pupil (mydriasis) occurs in complete loss of conscious-

¹ Amer. Jour. Med. Sci., Oct., 1909.

² Deut. med. Woch., 1902, No. 13.

ness, in severe pain, in dyspnea, in peripheral blindness (especially from optic atrophy and glaucoma), in general oculomotor paralysis, and in some cases of tabes dorsalis and progressive paralysis. Atropin, duboisin, cocain, chloroform (in the early stages of narcosis) dilate the pupil. Children, as a rule, have dilated pupils.

W. Riegel¹ describes, as a sign of neurasthenia, under the name of "alternating mydriasis," a dilatation appearing sometimes in one, sometimes in the other, eye with a normal reaction to light.

E. Redlich has described a pupillary phenomenon in hysteric individuals. It consists of a dilatation of the pupil (irresponsive to light, but reacting to accommodation) during a cry, powerful muscular action, or hysteric attacks. He refers this to an irritation of the sympathetic, and is of opinion that the phenomenon will explain the loss of pupillary response in many cases of hysteria, and that voluntary dilatation of the pupil is often due to a similar mechanism. There is the possibility, however, that in hysteria the dilatation and loss of pupillary reaction are due to the direct influence of the cortex upon the pupil. This has been proved in Haab's cortical pupillary reflex. (See p. 1059.) The loss of pupillary reaction during epileptic attacks and in meningitis is likewise in favor of a cortical pupillary rigidity, considering the localization of the causal process.

Irregularity in shape of the pupils may, of course, occur in diseases of the nervous system, but in most cases it depends upon some local disease in the neighborhood of the pupil (synechia). [One should guard against mistaking an irregular distribution of black pigment at the pupillary margin for irregularity of the pupil itself.—Ed.]

Inequality of the pupils is rare in health, and when present, most frequently depends upon an unequal refraction of the two eyes. It is not uncommon in the various unilateral cerebral affections, in progressive paralysis, in tabes dorsalis, in unilateral disease of the sympathetic, of the oculomotor, or of the optic nerve, and in migraine attacks. An inequality of the pupils is fairly common in neurasthenia, and is then usually of a vacillating character ("alternating mydriasis") (see above).

See p. 1058 et seq. concerning an inequality of the pupils which depends upon the loss of reaction and dilatation of one pupil.

On account of the *crossed pupillary reaction* (see below) both pupils are equally contracted when only one is exposed to light. Yet, not rarely, persons are observed in whom the pupil adjacent to the source of light is narrower than the shaded pupil. Too little attention is paid to the diagnostic significance of this phenomenon. It may be that it is a stigma of neurasthenia.

Anomalies of Pupillary Contraction.—*Pupillary Light Reflex.*—Exposure of the pupil to illumination narrows not only the pupil of the same side, but also the pupil of the other eye, thus giving rise to a direct and a crossed-light reflex or reaction. The part of the oculomotor nucleus (iris nucleus, see p. 1045) which innervates the iris must be considered as the center of this reflex.

A convenient method of testing the reaction of the pupils to light is as follows: With a moderate illumination (candle light) in front of the patient's face we alternately expose and then shade one eye with the hand, watching the effect of the light upon that pupil and upon the other pupil; then we do the same thing to the other eye. If the test with a moderate light does not produce the pupillary contraction, the examination should be repeated with a dazzling light (sunlight, an illumination lens, or a concave mirror).

¹ Zeit. f. Nervenheilk., 1900, vol. xvii, p. 169.

This customary procedure for the exact quantitative estimation of the reaction of the pupil to light is subject to a number of sources of error, which are due to the fact that the difference between the effect of light upon the macula lutea and upon the peripheral portions of the retina are disregarded, and also to the fact that the narrowing of the pupils by convergence and accommodation cannot be positively excluded. As a result of minute investigation, Schirmer¹ gives the following rules for the accurate study of the reaction of the pupils to light: "The patient should be seated at a distance of one meter from a well-lighted window which is not exposed to the direct rays of the sun. (See p. 1051.) After the eyes have adapted themselves to this illumination, the diameter of each pupil is observed; the reaction of each pupil to light is now determined by holding the hand in front of the open eyes and then rapidly withdrawing one of the hands. The reaction of each pupil to light is next determined while the opposite eye is unshielded from illumination." The reaction is more marked with the first method of examination (with the opposite eye shielded), since the exclusion of the crossed innervation causes the pupil to dilate before the reaction occurs, or, at least, to be more susceptible to light. This procedure is consequently the one best adapted for determining the vestiges of a diminished direct pupillary reaction. The crossed pupillary reaction is then determined by observing the eye, while the opposite one is alternately shielded and exposed. This investigation is repeated for each eye. The sum total of the direct and crossed pupillary reactions, and consequently the last remnants of a diminished reaction of the pupils to light, is best estimated by shielding both eyes, simultaneously exposing them, and then observing the reaction of both pupils.

Fig. 412.—Old diagram of the pupillary light reflex, which no longer obtains. The primary optic centers (pulvinar, corpus geniculatum externum, and anterior corpora quadrigemina) are represented as a single center for the sake of simplicity. (See Fig. 400.)

See p. 1056 et seq. concerning the so-called "hemiopic reaction," i. e., hemiopic rigidity of the pupil.

Fig. 412 represents the course of the light reflex which was formerly accepted as accurate. It was based upon the supposition that the stimulus to the iris nucleus, causing a reflex narrowing of the pupil, originated in the so-called primary optic centers (pulvinar, anterior cor-

¹ Deut. med. Woch., 1902.

pora quadrigemina, and corpus geniculatum externum, see Fig. 400). The bilateral character of the light reflex was attributed not only to the semidecussation of the optic fibers, but also to the bilateral connection of the iris nuclei. (See Fig. 412.)

Although the above conception was advocated in the earlier German editions of this work, it is no longer tenable, because it has been proved clinically, as well as experimentally, upon animals, that lesions of the primary centers do not cause any disturbances of the pupillary reflex. We must, therefore, conclude that the sensory fibers, which transmit the pupillary light reflex, are distinct from the visual fibers, and certainly leave the optic tract before its entrance into optic centers. Physiologic examinations and clinical observations induced Bechterew¹ to con-

Fig. 413.—Diagram of the pupillary light reflex. The continuous lines represent the visual fibers; the dotted lines, the centripetal fibers for the pupillary light reflex. The central tract for contraction of the pupil by convergence and accommodation is not indicated in the figure; it might be imagined as passing to the iris nucleus from the side.

clude that special pupillary fibers exist in the optic nerves and that these fibers, after separating from the visual fibers at a certain distance behind the chiasm, run through the gray matter near the third ventricle to the iris nucleus.

Owing to the occurrence of hemiopic pupillary immobility, it must be assumed that the fibers of the optic nerve which transmit the pupillary reflex undergo a semidecussation in the chiasm in the same manner as do the visual fibers.

Bechterew's diagram for the pupillary light reflex, which was reproduced in the second German edition of this work, does not sufficiently explain physiologic conditions; it contained no fibers whatever for the

¹ Deut. Zeit. f. Nervenheilk., vol. xvi, parts 3 and 4, p. 193 et seq.

direct pupillary reaction, and certain of its details had not been positively confirmed. The author believes that the following diagram (Fig. 413) of the pupillary reaction will explain the physiologic and pathologic facts now at our disposal without necessitating any further unwarranted suppositions. The previously mentioned and more recent anatomic postulates have been considered in its construction.

The lesions most important from a clinical standpoint are indicated in the diagram by the letters *a*, *b*, *c*, *d*, *e*, *f*, *g*, and *h*. The clinical symptoms of these lesions are as follows:

Lesion *a*: Transverse section of one optic nerve. Blindness and absence of the direct pupillary reaction in the eye of the same side, with retention of the crossed pupillary reaction. The crossed reaction is absent in the opposite pupil.

Lesion *b*: Sagittal section of the chiasm. Bilateral temporal hemiopia. The direct and crossed pupillary reactions are normal in both eyes when tested in the usual manner by diffuse light. Direct and crossed hemiopic pupillary immobility in both eyes (p. 1056, Note 2) from involvement of the nasal halves of both retinas.

Lesion *c*: Section of one optic tract in front of the primary optic center and before the partial decussation of the centripetal fibers for the pupillary reflex. Homonymous hemiopia and homonymous hemiopic crossed and direct pupillary immobility (see below). Normal direct and crossed pupillary reaction by the ordinary test with diffuse light.

Lesion *d*: Involvement of all the centripetal fibers of the pupillary light reflex upon both sides after their separation from the visual fibers. Absence of the crossed and direct reactions of both pupils to light, with retention of visual power, normal movements of the eyeballs, and normal reaction of the pupils for convergence and accommodation (Argyll-Robertson's symptom in tabes dorsalis and progressive paralysis, p. 1058).

Lesion *e*: Injury to the fibers connecting the centers. The direct and crossed pupillary reactions normal in both eyes when tested with diffuse light. But only the direct reflex is present when the temporal halves of the retinas are tested, and only the crossed reflex is present when the light falls upon the nasal halves.

Lesion *f*: Section of the centripetal fibers for the pupillary light reflex proceeding from the left halves of both retinas. Homonymous hemiopic pupillary immobility in both eyes upon illumination of the left halves of both retinas. With diffuse illumination the direct and crossed pupillary reactions of both eyes are normal. The visual power and pupillary reaction for convergence and accommodation are maintained in both eyes. (See p. 1059.)

Lesion *g*: Section of the motor fibers leading from one iris nucleus to the pupil of the same side. Immobility of the affected pupil to light, both direct and crossed, and also during convergence and accommodation. The opposite pupil reacts normally both to direct and crossed impulses, and also to accommodation and convergence. The acuity of vision and the visual fields are normal in both eyes.

Lesion *h*: Destruction of the left iris nucleus. Immobility of the left pupil, both to direct and crossed-light impressions and also during accommodation and convergence. This is associated with hemiopic immobility of the right pupil during illumination of the left halves of the retinas.

A number of direct observations are still necessary to demonstrate the complete accuracy of the diagram. No observations of types *e* and *f*, for example, have as yet been published. In type *h* investigations have not been made to determine whether hemiopic immobility of the opposite pupil is really present from an involvement of the retinal halves corresponding to the injured side. Not until positive statistics have been obtained in reference to these points can this diagram be defended as absolutely correct. If it be found that the lesions *e*, *f*, and *h* do not materialize in actual practice, the diagram must be modified.

Hemiopic Pupillary Immobility (Hemiopic Pupillary Reflex).—Fig. 413 furnishes a key to the comprehension of the so-called hemiopic pupillary reaction (Wernicke) or hemiopic pupillary immobility. When one side of the optic tract is injured at the point *c*, or when the centripetal fibers of the light reflex proceeding from homonymous retinal halves are injured in the neighborhood of the point *f*, the result must be that the light reaction from the corresponding homonymous retinal halves of both eyes will be entirely abolished, whereas from the opposite retinal halves the reflex will remain normal. To this peculiar condition Wernicke gave the name *hemiopic pupillary reaction*; but von Leyden quite properly substituted for this expression the term *hemiopic pupillary immobility*, because, as a matter of fact, when this condition appears, what is observed is certainly an immobility or rigidity. In order to demonstrate this rigidity it is essential, while watching the pupillary condition, that each retinal half be lighted separately.

The ordinary procedure consists in projecting a cone of rays into the eye from one side by means of an ophthalmoscope or of a focusing lens, and by observing the reaction of the pupils, according as the light impinges upon the left or upon the right retinal half. A darkened room is, of course, very desirable, if not essential. The difficulty in this depends upon the uncertainty of confining the illumination to one of the retinal halves. If the actual apex of the cone of light does not impinge upon the retina, anterior or posterior circles—radiations—of the light picture may affect the other retinal half or even the macula, and so spoil the test. According to Salomonsohn,¹ the best result can be obtained by reflecting upon the patient's face, from a concave mirror, placed horizontally beside the eye, a very sharp and vertical flame picture (the latter is collected by the mirror from an illumination situated at one side). Then, by turning the mirror slightly, the reflected light passes the pupillary edge and impinges upon the retina, first from the temporal, then from the nasal, side. It is essential that the patient should always focus at the same distance, preferably into space. On account of the difficulties mentioned above (the dispersed circles of light), the results from this method are oftentimes not very conclusive; hence the following modification may be attempted: A black screen, at least a meter square and with a central opening, is placed vertically in front of the patient in the dark room, at a distance of about 60 cm. (about 2 feet). While the patient focuses upon the opening, an assistant in front of the screen projects a very bright illumination (kerosene or electric lamp) into the visual field, at one time from the right and another from the left side, but not near the focusing point of the patient, and then the behavior of the pupils is noted through the opening in the screen. The lamp should always be held at about the same distance from the eyes as a focusing point, in order to be sure that a sharp flame and not dispersed circles are projected upon the retina; with this method the test can be made as well with one eye as with two. If the pupils of both eyes contract only when illumination is at the right side, or only when it is at the left side, right or left hemiopic homonymous pupillary rigidity is present.²

The difficulty of both these tests consists in the fact that ordinarily a stimulation of the peripheral portions of the retina by a circumscribed light picture excites

¹ Deut. med. Woch., 1900, No. 42.

² In the more unusual temporal form of hemiopia which characterizes tumors in the neighborhood of the chiasm (acromegaly) and hydrocephalus (in which the chiasm is compressed by the enlarged infundibulum), we are compelled to examine for hemiopic pupillary rigidity in the corresponding inner retinal halves. (See Fig. 413, lesion *b*.) But, as a matter of fact, the demonstration of hemiopic rigidity has no local diagnostic significance in this form of hemiopia, as it can arise only in the chiasm.

only a weak pupillary reaction unless the region of the macula¹ is actually stimulated as well. This objection applies particularly when the sensitiveness of the entire retina has been somewhat impaired, *e. g.*, with a choked disk. In such cases the following device may be helpful. Place in front of the patient a screen which rotates upon a sagittal axis, and one half of which is white, the other half black; then instruct the patient to focus upon a small mark in the black half of the screen near the border between the black and white, and suddenly illuminate the screen very brilliantly by means of a light placed behind the patient's head. Now, if the patient alternately open and shut his eyes, hemiopic pupillary rigidity can be demonstrated by the pupillary reaction occurring only when the white side of the screen corresponds to the normal retinal half. This method may be employed for one as well as for both eyes in homonymous hemipia; in heteronymous (temporal) hemipia, on the contrary, it can be used only for one eye.

In a case of acromegaly where even this device left the author in doubt, he employed the following method with considerable success. While the patient focuses upon some object (*e. g.*, his own fingers), at a distance of about 30 cm. (10 in.), an assistant projects in front of his eyes, at a distance of 30 cm., first from one side, then from the other, an electric bulb light of at least 32 candle-power, and stops just before the middle of the visual field; this light must be held so that the plane in which the carbon thread is bent remains parallel to the sagittal plane of the eye examined. With hemiopic rigidity the pupillary reaction can be obtained only from the retinal half whose pupillary fibers are preserved. The advantage of employing such an illumination is that by virtue of the linear character of the source of light, it remains sufficiently localized despite the presence of dispersed rays, to illuminate only one retinal half so long as the lamp does not approach too near the point focused. The great intensity of the illumination is an additional advantage.

Probably the best method of demonstrating hemiopic pupillary immobility known at present is performed by means of the "pupil tester," described by von Fragstein and Kempner,² which the author also has had an opportunity to employ. This is a small tubular instrument in which the rays from an incandescent lamp of 8 volts are condensed by lenses and diaphragms to a slender but most intense slightly convergent cone of light, the focus of which is situated 4 cm. in front of the anterior extremity of the instrument. With this cone of light it is easy to illuminate either half of the retina by projecting through the pupil from the temporal or the nasal side. Since the slightly convergent rays cross or become divergent 4 cm. in front of the instrument, an intense and quite circumscribed illumination of an individual portion of the retina is best assured by holding the instrument 3.3 cm. in front of the cornea, so that the focus of the cone of light falls about 7 mm. behind the convexity of the cornea. This situation corresponds to the nodal point of Listing's reduced eye, and rays passing into the eye and directed toward this point are peculiar in that they pursue their original direction through the vitreous humor as though they had not been refracted. With this position of the instrument the cone of light passes into the eye as though no refracting media were present, *i. e.*, the slightly convergent rays continue their original course into the interior of the eye as a slender, slightly divergent cone. This instrument is probably the only one with which it is possible to illuminate still more circumscribed retinal areas, such as a particular quadrant.³

The demonstration of hemiopic pupillary rigidity permits us to differentiate a so-called peripheral from a central homonymous hemipia. While, according to Fig. 413, peripheral hemipia (location of the lesion at *c*) produces hemiopic pupillary rigidity, this is not the case with central hemipia (location of the lesion at *e*, above the primary optic centers, Fig. 400). The hemiopic pupillary rigidity in which total double blindness, composed of two hemipias, one side of which is peripheral and the other central, occurs, is of special interest and has often been observed. An individual with these two lesions is completely blind. The accurate localization and significance of the visual disturbance then furnished by the presence of hemiopic immobility in the pupil which reacts only to one retinal half.

In those cases where hemiopic rigidity is present, both a direct and crossed

¹ Hess (Arch. f. Augenheilk., 1907, vol. lviii) showed that pupillomotor fibers exist only in the perimacular field, for a distance of about 3 mm., but not in the remainder of the retina. In a case of peripheral injury to one optic nerve Veraguth (Neurologisches Centralbl., 1908, No. 9) found that the pupillary reflex was lost though the eye retained a fairly large peripheral field of vision.

² Klin. Monats. f. Augenheilk., 1899.

³ This instrument may be obtained from Reiniger, Geppert, and Schall.

pupillary reaction can be obtained by testing the pupils in the ordinary way, so that both retinal halves receive light. The reaction may be diminished, but it is still plain enough. In order to avoid overlooking hemiopic rigidity the tests mentioned above must be accurately made, especially in all cases of homonymous hemiopic and bilateral blindness following a cerebral affection. It is clear (Fig. 413, lesion *f*), however, that homonymous pupillary rigidity may occur without any visual disturbance.

Certain other purely hypothetical conditions of hemiopic pupillary immobility have been given in the tabulation of the various lesions of the pupillary reflex upon p. 1055 et seq.

The technical difficulties in determining homonymous pupillary rigidity described above are perhaps the reason that the phenomenon has been so rarely found.

An additional difficulty is furnished by disturbances of Haab's so-called cortical pupillary reflex, which is brought about by concentration of the attention upon a lateral source of light. (See p. 1059.) All the procedures for testing hemiopic pupillary immobility are of such a character that the attention of the patient is apt to be concentrated upon the light itself. But this is, of course, the case only when the light falls on the normal retinal half, and, therefore, if Haab's reflex be lacking, hemiopic pupil rigidity may apparently be present when the blind retinal half is lighted.

Loss of Pupillary Light Reaction (Pupil then Ordinarily Dilated); Rigidity of the Pupil to Light.—A failure of the pupil to react to light occurs in severe disturbances of consciousness of the most varying kinds; in cerebral pressure (in these cases bilateral); in poisoning from the substances mentioned above as dilating the pupils (these unilateral or bilateral, depending upon the poison); in focal lesions which interrupt the reflex pupillary arc on one or both sides in the manner detailed in Fig. 413 (*e. g.*, motor lesions); in complete peripheral oculomotor paralysis; in nuclear oculomotor paralysis which affects the iris nucleus, but does not attack the other branches of the oculomotor (see p. 1045); in sensory lesions; in affections of the retina; and in bilateral optic atrophy or marked bilateral choked disk. Complete loss of pupillary reaction from choked disk is a comparatively exceptional occurrence, and observed only when the choked disk has caused blindness at the same time. The visual acuity is frequently very well preserved, and corresponds well with the slight injury to the conduction of the sensory fibers belonging to the pupillary reflex. Even when a lesion of the optic nerve diminishes the acuity of vision decidedly, the pupillary reaction need not be seriously impaired. This is evident without further explanation when we remember (p. 1054) that the centripetal fibers of the light reflex in the optic nerve are distinct from the visual fibers. A unilateral loss of reaction is usually associated with a dilatation of that pupil, as compared with the opposite side.

Ordinarily, complete examination of the condition of the optic nerve, on the one hand, and of the nerves supplying the eye muscles, on the other, facilitates a differential diagnosis between pupillary rigidity depending upon a lesion of the motor and that depending upon a lesion of the sensory segment of the reflex arc. Fig. 413 should always be consulted to comprehend the diagnostic points. In addition to other characteristics, it should be emphasized that with lesions of the motor segment of the pupillary reflex arc (in the nucleus of the iris or in the peripheral oculomotor), the narrowing of the pupil to accommodation and the power of convergence (see below under γ) is lost; whereas this is not the case when the loss of pupillary reaction depends upon a lesion of the retina or of the optic tract. In case the lesion is recognized as motor, the question is: Does this lie in the nucleus or its immediate neighborhood, or in the peripheral motor fibers of the oculomotor. This question is frequently decided by the behavior of the ciliary muscle, *i. e.*, by accommodation. In lesions of the nucleus or its neighborhood, accommodation may be preserved on account of the structure of the oculomotor nucleus (discussed upon p. 1045); whereas with a purely peripheral oculomotor paralysis, which may be situated in the trunk of the nerve or in the short branches of the ciliary ganglion, accommodation will probably fail.

Argyll-Robertson's Phenomenon (see p. 1055, *d*).—This is an early and important symptom of tabes dorsalis and of progressive paralysis. It consists in a preservation of the pupillary reaction to convergence and to accommodation, with a loss of the reaction of the pupil to light, and is not necessarily associated with any impairment of vision. (See p. 1059, γ .) For some unknown cause the pupils are generally narrowed (the so-called spinal miosis of tabetics).¹ Ordinarily the reaction of the pupils to pain is also wanting (see below under β). Erb called Argyll-Robertson's phenomenon a

¹ It has, however, not yet been proved that this is of spinal origin.

reflex pupillary rigidity, an expression in which the words, according to the author's opinion, are not used in their ordinary sense, since from it one might conceive of a rigidity occasioned reflexly, not of a rigidity of the reflex. The symptom has not yet been satisfactorily explained by anatomic researches. According to Bechterew, however, it must theoretically depend upon a lesion of all the centripetal fibers of the pupillary light reflex, either in the trunk of the optic nerve or after their separation from the visual fibers (lesion *d*, Fig. 413). It cannot depend upon a lesion of the motor segment (lesion *g* or *h*, Fig. 413), because the pupillary contraction in accommodation and convergence persists. F. Schultze noted the Argyll-Robertson pupil as a manifestation of toxemia in pneumonia. It is also frequently seen as a transitory phenomenon after epileptic attacks.

Paradoxic Pupillary Reaction.—This phenomenon, first described by Obersteiner and then by Bechterew, consists in the occurrence of a dilatation instead of a contraction of the pupils to direct and crossed illumination. At times a very insignificant initial contraction precedes the dilatation. Like the Argyll-Robertson phenomenon, this sign occurs principally in *tabes dorsalis* and *progressive paralysis*.

According to one conception, probably erroneous, this is a consensual or reflex dilatation depending upon unnoticed divergent movements of the eyeball at the moment of illumination (as contrasted with the narrowing of the pupils, associated with convergence and accommodation, see below, γ). Bechterew, however, considers that it is a phenomenon of fatigue, because, under the pathologic conditions mentioned above, a brilliant illumination fatigues, and so inhibits, the pupillary tonus after a scarcely noticeable or absent narrowing.

β . Pupillary Pain Reflex.—The stimulus of severe pains applied to various parts of the body, but more especially painful irritation of the skin of the neck, will usually dilate the pupils. This dilatation is produced by the pupillary dilator fibers of the sympathetic, derived from the eighth cervical and first dorsal segments. (See Fig. 462, p. 1149.) The reflex is sometimes useful in diagnosis, pointing to an involvement of the roots or of the sympathetic. According to the author's experience, however, the pupillary pain reflex in man is so inconstant that, generally speaking, a difference between the two sides is the only sign worth heeding.

γ . Narrowing of the Pupils to Convergence and to Accommodation.—Physiologically, the pupils are decidedly contracted by efforts at convergence or accommodation (it is difficult to separate one from the other). The consensual movement is diagnostically significant: in the first place, because it shows that in testing the other pupillary reactions we must be careful to have the patient avoid convergence or accommodation. Perhaps the best plan is to have him always focus for the same distance, preferably into space. A further diagnostic interest is furnished by the retention of the convergence and the accommodation reflex, while the light reflex is absent, which proves that the light reflex is not affected by a lesion of the motor tract.

(See above: Loss of Pupillary Reaction to Light, p. 1058; Argyll-Robertson's Phenomenon, p. 1058.)

δ . Westphal's Pupillary Phenomenon.¹—This consists of a contraction in the pupil when the examiner, by forcibly holding the lid open, prevents the patient's attempt to close the eye (Bell's phenomenon, p. 1075). To appreciate this reaction it is generally essential that the pupil in question should not react to light, or, at least, only slightly, and should not be markedly narrowed. It is most distinct when the pupils are dilated. Westphal never found the phenomenon in healthy individuals, and only once in the pupils of a hysteric person. He found it several times, on the contrary, in *tabes* and in *progressive paralysis*. The author has repeatedly observed it in *tabes*.

ϵ . Haab's So-called Cortical Pupillary Reflex.—Thus far no diagnostic significance has been attached to this reflex, though perhaps it may yet be utilized in the diagnosis of cortical disturbances of vision. It consists of a narrowing of the pupils when the patient, in a dark room, without any alteration in the position of the eye, concentrates his attention upon a flame placed at one side, i. e., seen indirectly.

9. Behavior of the Accommodation

Before testing the accommodation, the acuity of vision must first be determined and any error of refraction corrected. To correct the latter, if the patient be myopic, we employ the weakest concave lens

¹ Neurologisches Centralbl., 1899, No. 4.

with which he sees distant objects most clearly; if hypermetropic, the strongest convex lens. The acuity of vision is then determined in the ordinary way. The accommodation is then tested by placing before the eye under examination, at a distance of 25 cm. in a good light, the finest test-type which he should be able to read at this distance with his acuity of vision. (Perfect accommodative power presupposed.) If he can read this type, the accommodation is, at least, normal. If he cannot, his accommodation must be defective. Such a defect will consist of the physiologic presbyopia of his age, plus whatever accommodative paresis may exist. The convex lens which the patient requires for reading the selected type at 25 cm. distance (plus the glass which corrects the refraction) measures the defect of accommodation in diopters. By comparing this defect with that which is found in a patient as a result of the physiologic presbyopia for his age (see the accompanying table), we can decide whether there is a paresis or paralysis of accommodation. Should the patient need a + 4 D. lens to read the type clearly, there exists no power of accommodation.¹ Such a total defect is physiologic after the age of seventy-five years (see table); but in younger individuals it would indicate a complete pathologic paralysis of accommodation. If a patient forty-five years old require a glass of + 2 D. he has, in addition to his physiologic presbyopia (0.5 D., according to the table), a paralysis of accommodation of 1.5 D., etc.

Age.	Degree of presbyopia, i. e., the physiologic defect of accommodation in diopters.
Forty-five years.....	0.50 D.
Fifty "	1.50 D.
Fifty-five "	2.25 D.
Sixty "	3.00 D.
Sixty-five "	3.25 D.
Seventy "	3.75 D.
Seventy-five "	3.75 D.

We find a paralysis of accommodation in total oculomotor paralysis, in lesions of the accommodation nucleus (p. 1045), in diphtheric paralysis, and also after administration of atropin. Despite the fact that many diphtheric paralyses are probably peripheral in their localization, they are quite apt to involve the fibers of the oculomotor nerve which supply the ciliary muscle, whereas the pupillary fibers usually escape.

FIFTH CRANIAL NERVE; TRIGEMINUS

1. Motor Trigemini.—The motor branch of the trigemini supplies the muscles of mastication. Their power is tested by having the patient bite upon some object, such as a piece of cork or wood, or by having him exert vigorous movements of the jaw while the examiner attempts to hold the jaw still.

Unilateral weakness of the masseters may be recognized by placing, first on one side and then on the other, a flat piece of wood or spatula between the molars, and determining how firmly the patient can hold

¹ For the total optical effort required equals that which is necessary to focus upon the retina rays which come from a distance of 25 cm., in an eye rendered emmetropic by the correction of its refraction. This takes place when the convex lens in question renders parallel the rays which enter the eye from that distance. A lens of + 1 D. renders parallel rays which come from a distance of 1 m.; a lens of + 4 D. renders parallel rays which come from one-fourth of that distance, viz., 25 cm.

it by the action of these muscles. Palpation of the muscle itself during contraction also gives a good idea of its functioning power. The masseter also gives a good idea of its functioning power. The masseter muscle is best felt on the anterior border of the ascending ramus of the mandible, either through the cheeks or from the inside of the mouth. From the inside of the mouth we may also feel the contraction of the internal pterygoid, which lies opposite to the masseter and is separated from it by the mandible. The buccinator muscle is innervated by the trigeminus as well as the facial nerve. Its contraction can be felt by placing the finger in the mouth and directing the patient to press it actively against the alveolar process of the maxillary bone with his cheek. The mylohyoid and the anterior belly of the digastric are likewise innervated by the trigeminus, but this contraction is difficult to demonstrate. If, however, the patient with his mouth closed press his tongue against the hard palate, the floor of the mouth from the outside feels softer on the paralyzed side.

In regard to the action of the individual chewing muscles, we must remember that adduction of the lower jaw, *i. e.*, the closure of the teeth, is accomplished essentially by the temporal and masseter muscles. The external pterygoid pushes the lower jaw obliquely forward out of the glenoid fossa upon the articular tubercle (Gegenbauer). The bilateral action of the two external pterygoids protrudes the lower in front of the upper teeth. The unilateral action of one external pterygoid pushes the jaw to the opposite side, and the alternate action of the two external pterygoids—presupposing, of course, that the temporal muscle pulls the lower jaw back again into the glenoid fossa—causes the movement of mastication. The external pterygoid also aids in opening the mouth, and this is further assisted by the force of gravity, and by the digastric¹ and the platysma myoides muscles.² The internal pterygoid muscle aids the temporal and the masseter in adducting the lower jaw, and also contributes, to a certain extent, in the movement of the jaw forward.

Cerebral *paralyses of the chewing muscles* are analogous to cerebral paralyses of the eye muscles. (See p. 1039.) They are always to be attributed to a cause lying in the neighborhood of the trigeminus nucleus or affecting the efferent trigeminus fibers. This depends upon the fact that above the nucleus the central fibers of each trigeminus are distributed to both hemispheres, in consequence of which a unilateral hemispheric lesion does not necessitate a crossed motor trigeminal paralysis, as the function of the intact hemisphere is sufficient to maintain the innervation of both sides. To comprehend this bilateral innervation, the reader should consult Fig. 403, for that diagram applies to the muscles of mastication in the same way as to the eye muscles. On the other hand, a bilateral paralysis of the chewing muscles can be brought about by bilateral hemispheric lesions, such as pseudobulbar paralyses (p. 1090). In hemiplegia a bilateral defect of innervation of the chewing muscles may perhaps be demonstrated with the dynamometer.

Spasm of the chewing muscles occurs as an accompaniment of general spasms, *e. g.*, the tonic spasms in tetanus and in meningitis, and reflexly from painful affections of the jaw, producing so-called lockjaw.

The so-called *jaw reflex* depends upon both the motor and the sensory trigeminus. It consists in a contraction of the chewing muscles which lifts the lower jaw, and is produced by striking the lower jaw, either directly with a percussion

¹ The anterior belly is innervated by the third branch of the trigeminus; the posterior belly, by the facial.

² Innervated by the facial.

hammer or indirectly through some object applied to the jaw. It can be elicited in most healthy individuals, but is not absolutely constant. If the reflex be increased, a clonus can frequently be elicited by simply drawing the jaw downward (jaw-clonus, masseter-clonus).

The Palate Function of the Trigemini.—The trigemini takes part in the innervation of the soft palate, and supplies in great part the posterior arch, according to observations of paralysis of the trigemini.¹ In unilateral paralysis of the motor root of the trigemini the posterior arch of the palate hangs lower than that of the normal side, the uvula is twisted anteriorly and toward the paralyzed side. The latter phenomenon is not easy to explain, but it seems to be due to the fact that the side of the uvula corresponding to the posterior arch of the palate which hangs down is shortened and made tense, becoming concave on that side in a manner similar to the spring of an aneroid barometer. The bending forward is probably due to the fact that the dropping of the posterior palatine arch lessens the space at the posterior aspect of the uvula.

Auditory disturbances (diminution of hearing and subjective tinnitus) in cases of trigeminal paralysis have been referred to a paralysis of the tensor tympani. These symptoms are, however, inconstant and capable of many interpretations.

2. Sensory Trigemini.—The sensory division of the trigemini supplies the skin of the face, the mucous membranes of the mouth and nasal cavities, the conjunctiva, and the cornea. It also takes part in the function of taste (chorda tympani), and the function of smell in the nasal mucous membranes. The sensibility of the skin (touch, pressure, pain, and temperature) is tested just as was described above (p. 967 et seq.). In testing the trigemini taste function, a soft brush moistened first with acid (weak acetic acid) and afterward with salt solution is touched to the tongue, and the patient asked to describe what sense of taste he experiences. The two sides of the tongue are compared, and it is readily determined whether the appreciation of taste is equally active and prompt upon the two sides. Since the trigemini practically supplies only the anterior part of the tongue, the test should be made there, so as to exclude, so far as possible, the taste-fibers of the glossopharyngeal. The patient should keep his tongue protruded, and reply to the examiner's questions by nodding and shaking his head. It is, of course, advisable to include at the same time the examination of the sense of taste of the part supplied by the glossopharyngeal, employing the same method as above, but selecting the posterior part of the tongue. The patient should not breathe during the test, so as to avoid a confusion between the sense of smell and that of taste. The taste-fibers of the trigemini (chorda tympani) may be injured in lesions of the lingual muscle (which they supply), in affections of the middle ear (through which they pass), in certain peripheral paralyses of the facial (see pp. 1070 and 1071), and finally in lesions of the root of the second or, according to other authorities, of the third branch of the trigemini, in which the taste-fibers are diverted from the facial. (See Fig. 422.) Testing the sense of smell supplied by the trigemini has been described already under the olfactory nerve. (See p. 1033.)

The *corneal sensibility* is determined by touching the cornea with the head of a pin. Normally, this procedure is rather painful, owing to the fact that, according to von Frey's researches, the cornea possesses no tactile points, but probably countless pain points. (See p. 968 et seq.) At the same time we should determine the preservation or absence of the so-called "corneal reflex" (lid closure in touching the cornea). The loss of this may depend upon a lesion of the sensory segment (tri-

¹ C. W. Müller and F. Schultze.

geminus), or of the motor segment (facial) of the reflex arc. Further examination will determine which.

Pareses of the sensory trigeminus occur in peripheral lesions of the nerve, in lesions of the trigeminus fibers emerging from the pons, and also accompany the hemianesthesias observed both in hysteria and in focal lesions at the most posterior part of the internal capsule. (See p. 1090 et seq.) Disturbances of sensibility which appear in the region supplied by the trigeminus from spinal cord affections involving the ascending (spinal) trigeminus roots are worth noting, because of their diagnostic importance. They may occur as low as the second cervical segment (syringomyelia).

(See Fig. 449, p. 1136, in regard to the distribution of the peripheral skin branches of the trigeminus.)

The peculiar so-called trophic disturbances of the conjunctiva, the mucous membrane of the mouth, and the cornea, caused by lesions of the sensory part of the trigeminus, are of interest, although the significance of the phenomenon has not yet been determined. Some assume that it is merely a diminution of the self protection of the tissue, because of the lost sensibility and the destruction of certain vasomotor reflexes. Others believe it to be due to the direct trophic influence of the sensory fibers of the trigeminus. Whichever explanation be correct, there is no doubt that so-called trophic disturbances occur and are directly connected with sensory trigeminus paralysis. The author once saw an exquisite neuroparalytic keratitis in a case of brain tumor, with almost complete paralysis of the sensory trigeminus. In this case, and also in a case of tabes with trigeminus anesthesia, peculiar ulcers developed at the corner of the mouth and on the buccal mucosa, which at first glance had the appearance of syphilitic or carcinomatous lesions. They were distinguished, however, by their very slight infiltration and a tendency to cicatricial contraction and healing. In the case of brain tumor, a trophic disturbance appeared on the outer surface of the cheek in the form of vesicles, caused by the moderate heat used in the test for thermal sensibility, while the normal side remained uninjured. In this case the trophic disturbances could not be explained by a disturbance of the vasomotor reflex, because gentle mechanical irritation of the skin produced a hyperemia similar to that of the healthy side. The objection to the assumption that sensory fibers can conduct direct centrifugal trophic impulses can no longer hold, because studies in the negative variations of currents have furnished direct experimental physiologic proof that motor and sensory fibers can conduct impulses in both directions, *i. e.*, sensory fibers can conduct centrifugally.

SEVENTH CRANIAL NERVE; FACIAL

The facial nerve, probably purely motor, supplies the facial muscles, including the muscle which closes the eye (*orbicularis oculi*), Horner's muscle, the *platysma myoides*, the muscles of the scalp (*occipitalis* and *frontalis*), the *retrahens*, *attolens*, and *transversus auriculæ*,¹ the *stylohyoid*, the posterior belly of the *digastric*, the *buccinator*, and finally, by means of the descending palatine nerves, which pass through the sphenopalatine ganglion of the second branch of the trigeminus it supplies, together with the *glossopharyngeus*, *vagus*, and *spinal accessory*, the muscles of the soft palate. The facial supplies the greater part of the latter. The *palatoglossal* and *palatopharyngeal* muscles (*palatine arch* and the *azygos uvulæ*) seem to be supplied mostly by the facial. In the Fallopian canal the facial nerve supplies the *stapedius* muscle by means of the *stapedius* nerves. At one part of its course in the temporal bone the *chorda tympani* is united to the facial nerve, contributing the taste-fibers to the facial, and receiving from it the salivary secretory fibers for the submaxillary and sublingual glands. (See p. 1070.) From its motor nucleus the facial receives fibers for sweat secretion, and, according to Goldzieher, the secretory fibers for the lacrimal glands. These, Köster² thinks, probably originate from the nuclear region of the *glossopharyngeal*. (See p. 1071.) At the periphery the facial oftentimes receives sensory fibers of the trigeminus.

¹ According to Heitzmann, the *attrahens auriculæ* is supplied by the auriculo-temporal branch of the third branch of the trigeminus.

² Arch. f. klin. Med., vol. lxviii.

(a) Paralysis of the Facial

General Symptomatology of Facial Paralysis.—Upon the paralyzed side in facial paralysis we notice an obliteration of the wrinkles, a loss or very slight preservation of the ordinary voluntary movements, and, under some circumstances, even the loss of the emotional movements, the associated movements, and the reflexes. If the paralysis be sufficiently marked, the affected cheek flaps with respiration like a boat's sail, especially during sleep, and if the branches to the eye be affected, the eye remains more or less open, despite attempts to close it and even during sleep (*lagophthalmus*). In early cases the mouth is drawn to the healthy side. If the palate also be paralyzed, it frequently hangs noticeably lower upon the diseased side and seems drawn to the healthy side, and voluntary or reflex movement draws it still more toward the latter. An oblique position of the uvula so often occurs normally that it is of no importance for the diagnosis of palate paralysis. (See p. 1062 in regard to the oblique position of the uvula and the behavior of the palate in motor paralysis of the trigeminus.) A unilateral palate paralysis will produce neither a nasal character in the voice nor regurgitation through the nose; but both phenomena will be observed if the palate be bilaterally paralyzed (diphtheric paralyzes). If the eye be prevented from closing by an accompanying movement of the ocular branch of the facial, the normal flow of tears will be affected by paralysis of Horner's tear-sac muscle and a drooping of the lower eyelid. The patient will then suffer from a trickling of tears (epiphora), and very often eczema of the eyelid results. He may also complain of slight disturbances of vision on account of the corneal suffusion. *Blepharoplegia* (loss of automatic winking) is marked even in complete facial paralysis (including the *orbicularis oculi*). This signifies that winking depends not merely upon facial innervation, but also upon relaxation of the *levator palpebræ superioris*. In consequence of the disturbances of the flow of tears the nasal mucous membranes become drier than normal, and the sense of smell is, therefore, often affected. The nasal opening of the diseased side often seems narrowed from paralysis of the *levator alæ nasi*. Because of the paralysis of the muscles about the lips, the saliva frequently trickles from the corner of the mouth upon the paralyzed side and patients are unable to whistle. With pronounced facial paralysis the speech may be altered, especially the ability to articulate the labial letters. Statements vary considerably in regard to the condition of the tongue in facial paralyzes. Probably facial paralysis as such has no influence upon the position of the tongue, although, since the facial nerve innervates the stylohyoid and the posterior belly of the digastric muscle, its paralysis may have a certain influence upon the position of the hyoid bone. In central facial paralysis the tongue deviates toward the paralyzed side, because here the hypoglossal nucleus, situated so near by, is always more or less affected as well. The deflection of the tongue in central facial paralysis is, therefore, the result of a paresis of the genioglossus muscle, which is supplied by the hypoglossal nerve. (See Twelfth Cranial Nerve, p. 1086.) Deflections of the tongue occur in peripheral paralysis, but these have only an indirect connection with the facial nerve, and their explanation is not the same in every case. For instance, in peripheral paralysis one would think at first glance that the tongue was protruded obliquely, but more

careful observation shows that it is really protruded in the middle line, the appearance of deviation being due to the twisted mouth. In other cases the tongue is actually deflected to the healthy side, which is exactly opposite to the condition in central facial paralysis accompanying genioglossus paralysis. Hitzig has proved that this depends upon the patient's effort to protrude his tongue obliquely in order to keep it in the middle of the twisted mouth. This can be confirmed easily by correcting manually the asymmetry of the mouth. The patient then protrudes the tongue exactly in the middle. Paralysis of the platysma myoides is most readily recognized by having the patient attempt to draw the lower lip downward as far as possible. Normally, the platysma assists in this movement, and the contracted fibers stand out quite

Fig. 414.—Facial asymmetry simulating hemiplegia. The distorted nose and a groove in the lower front teeth are responsible for the apparent deviation of patient's tongue to the right (New York City Hospital).

plainly under the skin of the neck, so that the contrast between the healthy and paralyzed sides can be readily recognized. A paralysis of the muscles of the ear (retrahens, attollens, and transversus auriculæ) and of the frontalis and occipitalis muscles can be readily recognized, but only in those patients who can move the ears and the scalp voluntarily. Yet, sometimes a paralysis of the ear muscles of one side causes a noticeable drooping of the ear.

The clinical picture of facial paralysis varies, moreover, according to the position of the paralysis, whether above the nucleus (*i. e.*, in the central neuron) or in or below the nucleus (*i. e.*, in the peripheral neuron). It becomes necessary, therefore, in the following discussion, to differentiate accurately the symptomatology of these two types of facial

paralysis, and to defer the discussion of the affections of secretion and taste as well as certain accompanying troubles with the hearing, until the peripheral type (the one which they accompany) is taken up.

Central (Supranuclear) Facial Paralysis.¹—As is well known, the cortical center of the facial nerve lies at the foot (*i. e.*, the lowermost part) of the central convolution (see Figs. 424, 425, and 426, p. 1095), and from this point its fibers pass intermingled with the other pyramidal fibers through the internal capsule to the facial nucleus of the opposite side. In its course it is quite frequently injured (cerebral hemiplegia). Any lesion situated above the nucleus causes what we designate as central facial paralysis, involving the muscles of expression of the lower half of the face and the corresponding half of the palate upon

Cortical center

Peripheral nucleus

Fig. 415.—Diagram of the central innervation of the facial nerve. The upper branch is supplied from both hemispheres, more from that of the opposite side. The lower branch is supplied almost exclusively from the opposite hemisphere.

the affected side, whereas the secretory and taste functions of the facial are not affected at all, because the fibers supplying them do not join the facial nerve until it reaches the periphery. (See Nucleoperipheral Facial Paralysis.) Nor does this paralysis include the upper branch of the facial, which supplies the muscles for closing the eyes and the forehead muscles, for reasons about to be mentioned. In regard to the behavior of the tongue, see above, p. 1064.

The most weighty factor in differentiating between a central and a

¹ "Central" and "cerebral" should not be confused. A subnuclear or peripheral facial paralysis may be located within the brain, *i. e.*, still be cerebral, although it is below the nucleus, and therefore not central, but peripheral.

peripheral paralysis is the non-involvement of the upper facial branch (for the forehead and eyes) in the former. This peculiarity is to be explained by the supposition that only the lower part of the facial (the branch to the face) possesses an actual crossed innervation from the cerebral cortex, whereas the upper branch, like the eye muscles (see p. 1043) and the motor trigeminus, is equally innervated or nearly so by both hemispheres, so that any defect of innervation from one hemisphere is concealed or compensated for by the activity of the other.

A diagram of the central facial innervation, made in accordance with this supposition, is given in Fig. 415. This clearly explains how a unilateral cerebral lesion at (a) paralyzes only the lower, not the upper, facial of the opposite side, since the latter is still sufficiently innervated by the uncrossed tract.

The hypothesis responsible for Fig. 415, viz., that the facial possesses a separate nucleus for its lower and another for its upper branch, is really not based upon anatomic proof. But experience shows that a bulbar paralysis, a disease of the nuclei of the oblongata, affects almost exclusively the lower facial, which makes it probable that the nucleus of the latter exists functionally isolated, even though it is impossible to demonstrate this macroscopically. We have attempted to express this individuality as simply as possible in Fig. 415, by representing the two facial nuclei as connected.

It is, moreover, incorrect to assume that in a central paralysis the upper facial escapes entirely, for a more minute examination shows that a slight weakness can ordinarily be demonstrated. This consists in a less vigorous closure of the eye upon the affected side, and in the patient's inability to close the eye of the paralyzed side alone, although before the injury this was possible (*signe de l'orbiculaire*, Revilliod). From this it is evident that both hemispheres influence the upper facial, but that the effect of the crossed fibers outweighs that of uncrossed, although perhaps only to a slight extent. Fig. 415 suggests this by the heavier line representing the crossed fibers of the upper facial.

Probably the central innervation of the stapedius muscle, which plays a rôle in the symptomatology of peripheral facial paralysis, behaves in the same way as that of the upper facial, so that in consequence of the bilateral innervation of the stapedius the symptom of hyperacusis (p. 1070) cannot be attributed to central facial paralysis.

In addition to the escape of the upper facial innervation, a central facial paralysis is further differentiated from a peripheral paralysis by the way in which certain voluntary movements and the emotional movements take part in the paralysis. To explain this point we must assume that tracts which are separated at least for a part of their course are responsible for each different kind of movement. Fig. 416 will serve as an illustration.

Fig. 416.—Diagram of the three functionally different central paths of the facial nerve and of its reflex arc.

a Represents the psychomotor center of the facial; *b* represents another psychomotor center (*e. g.*, the arm-center); *c*, the optic thalamus; *d*, the facial nucleus.

The tract (*a d e*) represents the voluntary facial tract.

It has been assumed oftentimes that associated movements (*e. g.*, grimaces accompanying movements of an arm) depend upon hypothetical tracts like *b d*. To prove their existence it has been argued

2

Fig. 417.—Facial palsy of left side: 1, Attempt to raise both eyebrows; 2, attempt to close both eyes; 3, smiling (Church).

that a slight central facial paralysis is sometimes evidenced only by a weakness of the associated movements, as compared with those of the healthy side, thus assuming the injury of a tract (*b d*), while the actual facial tract (*a d*) is unaffected. But this manifestation of a weakness of the associated movements in the facial territory in certain cerebral facial paralyses can also be explained in another way. The associated move-

4

5

6

Fig. 418.—Facial palsy of left side: 4, Forced effort to uncover teeth on both sides; 5, protruded tongue in middle line; 6, mouth open more widely on sound side in bilateral effort (Church).

ments can be assumed to pass along the tract (*b a d*). Then a slight lesion of the voluntary tract, *a d*, offers no appreciable opposition to the voluntary impulse, but does to the weaker associated impulse running over *b a d*. The fact that a similar effect has been noted in mild cases of peripheral paralysis argues for this explanation (p. 1069, note 1). Hence it seems to the author superfluous to assume the existence of tracts like *b d* in order to explain associated movements.

The facial innervation of mimicry is probably from the tract *c d*, through the optic thalamus. This is determined from experience in affections of the optic thalamus or of its neighborhood, which cause isolated paralysis of the facial mimetic movements. Moreover, if the thalamus region be intact, ordinarily no, or only a very slight, involvement of the mimetic movements occurs in facial paralysis.

7

8

Fig. 419.—Facial palsy of left side: 7, Effect of faradism on sound side; 8, non-effect of same current on paralytic side (Church).

Besides the relative freedom from involvement of the upper branch, a central facial paralysis is characterized by intact reflexes and by the fact that the actual voluntary movements and the spontaneous movements need not be affected to the same degree, whereas without question, in lesions of the peripheral neurons situated somewhere along the line

9

Fig. 420.—Same case six months later. 9, Shows late contracture on the parietic side while the face is at rest; 10, contracture in the lower half of the face increased by gently closing the eyes, and at the same time shows weakness about left eye; 11, contracture increased by raising brows, showing overaction of zygomatici and weakness of frontalis on left side (Church).

d e (i. e., in nucleoperipheral paralysis), both functions appear to be equally affected.¹

In order to differentiate a central from a nucleoperipheral facial

¹ This is true, however, only for very decided and complete nucleoperipheral facial paralyses. In incomplete peripheral paresis, one frequently observes merely that the facial behaves differently for different kinds of movements, *e. g.*, that the paralysis is recognized only in laughing or in associated movements. Perhaps this can be explained by supposing that in the different kinds of movements (voluntary, spontaneous, associated, and reflex movements) the impulses vary in strength.

paralysis, it is obviously necessary to distinguish separately the different kinds of facial movements, to carry out the electric examination in accordance with the rules mentioned upon p. 1009 et seq., and to determine the presence or absence of degenerative atrophy of the paralyzed muscles in accordance with p. 1000 et seq. Of course, neither atrophy of the facial muscles nor electric changes occur in central facial paralysis.

Nucleoperipheral Facial Paralysis.—The general symptomatology of facial paralysis mentioned above (p. 1064 et seq.) must be amplified in the case of nucleoperipheral paralysis by the description of certain other disturbances of function peculiar to this type.

As most important may be mentioned the paralysis of the stapedius muscle. The motor fibers for the supply of this muscle leave the facial nerve within the petrous bone in order to reach the tympanic cavity. (See Fig. 421, p. 1072.) Although they probably also accompany the facial in its intracranial course, a stapedius paralysis is actually observed only in the peripheral form of facial paralysis, probably because the stapedius muscle, like the forehead and eye branches of the facial, is innervated by both cerebral hemispheres. (See p. 1067.) This paralysis of the stapedius, observed in certain localizations of peripheral facial palsy, of which we shall speak later more fully, is sometimes manifested by a characteristic peculiarity of hearing, designated as hyperacusis. In this condition the patient hears the deep tones (and sometimes others) louder upon the paralyzed side, and oftentimes in a very annoying fashion; sometimes the sound impression is combined with a sensation of pain. Lucae has attributed this phenomenon to an increased tension of the tympanic membrane, producing a rise of pressure in the labyrinth, because the action of the tensor tympani (innervated by the trigeminus) can be no longer counteracted by its antagonist, the stapedius. This explanation coincides with the modern conception, which assumes that the tympanic membrane, together with the chain of ossicles and their muscular apparatus, serves much less for sound transmission than for a so-called accommodation of the acoustic organ to the different kinds of sound impressions, and for the protection of the internal ear against too intense sounds, associated with marked pressure variations in the labyrinthine fluid. Patients with paralysis of the stapedius muscle also occasionally complain of experiencing subjective noises in the ear from movements of the facial or chewing muscles.

Other peculiar phenomena occur in peripheral facial paralysis when the fibers of the *chorda tympani* are injured. These consist partly of disturbances in the senses of touch, of pain, and of taste upon the anterior half of the tongue, partly of disturbances in the salivary secretion of the submaxillary and sublingual glands. Patients frequently complain of a defective sense of taste upon one side of the tongue, or of an abnormal dryness of the corresponding half of the mouth. (See p. 1062 et seq. for the more exact method of testing the sense of taste.) To examine the chorda tympani's function of salivary secretion more accurately the following procedure is advisable: The patient opens his mouth and lifts the tip of his tongue so as to expose the openings of the ducts of the submaxillary and sublingual glands (ordinarily united at the sublingual caruncle). In case he is unable to do this, the tip of the tongue is held up by a pair of tongue forceps. The sublingual caruncle is then carefully dried upon both sides of the frenum with absorbent cotton, and while the examiner watches carefully the openings of the

ducts, the patient inhales deeply the fumes from a sponge saturated with acetic acid, and held close to the nose. If the chorda functionate normally, the saliva flows from both sides freely, as a result of the reflex; if the chorda be paralyzed upon one side, the flow occurs only upon the healthy side or much more profusely upon that than upon the injured side.

The excretory ducts are occasionally so close together that the above method will not enable us to determine whether saliva comes from one or both openings. In these cases the author has succeeded in gently clamping the excretory duct upon the unaffected side with a cilia forceps, after which it is easy to observe whether saliva escapes from the opposite opening.

In connection with the anatomic relations of these two functions of the chorda to the facial, we should emphasize the fact that the function of secreting saliva belongs to the facial from its origin at the base of the brain up to the exit of the chorda tympani. According to Köster,¹ it probably does not arise from the facial nucleus itself, but from the nuclear region of the portio intermedia Wrisbergi belonging to the glossopharyngeal. The taste-fibers of the chorda tympani, on the contrary, accompany the facial from the periphery through the tympanic cavity, merely a tiny distance apart, and leave the latter again near the geniculate ganglion in the petrous bone (Fig. 422), according to one supposition (continuous blue line), in order to connect with the sphenopalatine ganglion by means of the large superficial petrosal nerve, and from there with the second branch of the trigeminus, but according to another less probable view (dotted blue line) in order to connect with the third branch of the trigeminus or with the glossopharyngeal by means of the communicating nerve to the tympanic plexus.

Our knowledge of the functions of the peripheral facial has been still further perfected by Goldzieher. He found that at the base of the brain the trunk of this nerve contains fibers for the secretion of tears, and that, therefore, an injury to the facial at this point results in drying up the tear secretions² upon the paralyzed side. These secretory fibers must emerge from the facial further down in the region of the geniculate ganglion and pass by means of the greater superficial petrosal nerve to the sphenopalatine ganglion, and from there to the lacrimal glands, by means of the communication between the subcutaneous malar and the lacrimal nerves. Goldzieher's suppositions have been confirmed by an observation of Franke,³ as well as by the extensive clinical and experimental work of Köster.⁴ According to the latter, the lacrimal secretory fibers, like the salivary secretory fibers, probably arise from that part of the glossopharyngeal nucleus belonging to the portio intermedia Wrisbergi, and mingle with the facial directly at its exit from the brain. To test the lacrimal secretion, he recommends tickling the nasal mucous membrane with a feather or with a fine brush, and then observing the secretion. The amount of the tear-flow secreted can be best estimated by collecting it upon a piece of filter-paper introduced into the conjunctival sac.

Köster, in addition, showed that disturbances of the sweat secretion

¹ Deut. Arch. f. klin. Med., 1900, vol. lxxviii.

² That is, there is only intermittent secretion from the tear-glands, such as occurs in weeping or in reflex tears, not a continued conjunctival secretion.

³ Deut. med. Woch., 1895, p. 33.

⁴ Loc. cit.

upon the paralyzed half of the face appear not uncommonly in peripheral facial paralysis. This, too, is to be attributed to the fact that from its nucleus the facial conducts fibers for the secretion of sweat. In peripheral facial paralysis these fibers may be stimulated (hyperhidrosis) as well as paralyzed (anhidrosis). These phenomena may be confused with the influence of the sympathetic upon the sweat secretion of the face.

Slight disturbances of hearing readily occur in lesions of the facial nerve in the neighborhood of the geniculate ganglion. These depend

Fig. 421.—Diagram of the peripheral nerve-fibers of the facial for clinical use.

upon the proximity of the internal ear to the facial nerve at this point (the cochlea is separated by a layer of bone about $\frac{1}{4}$ mm. thick). Hence inflammatory changes of the facial can easily affect the internal ear.

The distinctions between nucleoperipheral (i. e., facial paralysis in the region of the peripheral neurons) and central facial paralysis have already been emphasized in describing the latter (p. 1066 et seq.). From this it is evident that the essential factors in the distinction are the definite paralysis of the forehead and eye branch of the facial in the nucleoperipheral forms, disturbances in the secretory and taste functions,

the condition of the tongue (p. 1064), the condition of the reflex and spontaneous movements (p. 1068), and the electric and trophic conditions of the muscles. After the nucleoperipheral nature of a facial paralysis has once been recognized, the chief interest centers in determining the exact location of the lesion in the course of the nucleoperipheral

Fig. 422.—Diagrammatic plan of the peripheral facial nerve and its connections with other nerves:

- Motor fibers of facial.
- Other cranial nerves.
- Secretory fibers of the facial to the submaxillary and sublingual glands and of the glossopharyngeal to the parotid.
- Taste-fibers of the facial from the chorda tympani.
- Central course of the same from the geniculate ganglion according to another less probable theory. (Termination through the nervus tympanicus (Jacobson's) in the glossopharyngeal or through the otic ganglion in the third branch of the trigeminal.)

tract. This is best accomplished by referring to the diagrams (Figs. 421 and 422). Fig. 421 serves for general orientation; Fig. 422, for a comprehension of the anastomoses of the facial nerve.

In Fig. 421 it is evident that a lesion situated at *a* will affect only the so-called mimic branches of the facial, including the platysma myoides; if it be situated at *b*, above the exit of the facial from the

stylomastoid foramen, the posterior auricular nerve will also be paralyzed (this supplies the occipital muscle and the attolens, retrahens, and transversus auricular muscles).¹ As many people cannot move these muscles voluntarily, paralysis of them is oftentimes shown only by an electric examination, and then, of course, only when the electric irritability of the paralyzed muscle has been impaired. If the lesion be situated at *c*, the taste and the salivary secretory fibers of the chorda tympani are also paralyzed. This becomes evident in a diminution of the trigeminus taste appreciation upon half of the tongue in its anterior portion and possibly in a dryness of half of the mouth. (See p. 1071 for a more exact method of testing this function.) The sensations of touch and pain in the anterior half of the tongue are sometimes diminished, since the chorda tympani also contains fibers for the appreciation of touch and pain in the tongue. With a lesion at *d*, the stapedius muscle, supplied by the stapedius nerve from the facial, shares in the paralysis. (See above, p. 1070, in relation to phenomena so caused.) Should the lesion be situated still farther above at *e*, that is, above the geniculate ganglion, the disturbances of taste just mentioned escape, because the taste-fibers have left the facial at this point, but half of the palate will be paralyzed to voluntary and to reflex (see p. 1075) impulses, and the secretion of tears (see p. 1071) may be affected. Disturbances of hearing from an extension of the process to the cochlea may result from lesions in the neighborhood of the geniculate ganglion. (See p. 1072.) If the lesion be situated at *f*, at the base of the brain, where the acoustic and facial nerves are so closely approximated, the former is oftentimes involved with the latter, and in addition to the involvement of the tear secretion, diminution of hearing and disturbances of equilibrium from lesions of the fibers of the ramus vestibuli are added to the symptoms of facial paralysis. The changes in the cutaneous secretion on the side of the facial paralysis mentioned on p. 1072 have no diagnostic importance, because they may either be absent or present in any situation of the lesion. When the lesion is localized still higher up (*i. e.*, is nuclear) (*bulbar paralysis*), the coincident involvement of other bulbar nerves, the bilateral character of the paralysis, and the very unequal involvement of the individual branches of the facial make the picture sufficiently characteristic. In bulbar paralysis the territory of the lower facial (see p. 1064) is most affected, especially the lip musculature. The facial palsy due to a lesion in the pons, another nucleoperipheral palsy, since the peripheral motor neuron is also affected, is usually characterized by paralysis of the extremities upon the opposite side (alternating or crossed paralysis). This is due to the involvement of the psychomotor tract for the extremities (the pyramidal tract) before its decussation, although at this point the facial fibers have already crossed. Between this location and the cortex is the region for central facial paralysis.

In addition to these local diagnostic points (in regard to the special symptomatology of nucleoperipheral facial paralysis), the following facts will be of assistance in completing the clinical picture:

Lagophthalmus, due to paralysis of the eye branch, is a very characteristic sign in most cases of peripheral facial paralysis, and one which furnishes a sharp contrast to central facial paralysis. This con-

¹ According to Heitzmann, the attrahens auricular muscle is supplied by the auriculotemporal nerve from the third branch of the trigeminus.

sists in the eye on the paralyzed side remaining open during sleep and despite attempts to close it. In fruitless endeavors to close the eye the globe assumes the so-called sleeping position, upward and outward, more rarely upward and inward, beneath the upper lid, so that patients believe that they have completely closed the eye.

This so-called "*Bell's phenomenon*," just described, is to be attributed to an associated movement of the globe, whose object is to protect the eye. It occurs physiologically, as is shown by its appearance during sleep in a healthy individual, as well as by the fact that it also occurs when a healthy person attempts to close the eye when the closure is mechanically prevented.¹ The sign is more evident in paralysis of the eye branch of the facial, not only because the eye remains open, and so we see it more plainly, but also because the movement appears to be increased, probably because, after interruption of conductivity in the domain of facial branches, the motor impulses radiate more intensely through the pathway of the associated movement in a way quite analogous to other associated movements. Bell's phenomenon has some prognostic significance, as one of the earliest signs of improvement in facial paralyzes is a retrogression of this sign. This is probably to be attributed to an improvement in the conduction function of the facial fibers, whereby a smaller proportion of the motor impulses are diverted into the branch for associated movements; with this improvement of transmission the strength of the motor impulses, corresponding to the better effect, is diminished.

[Instead of Bell's phenomenon, another very interesting condition has been observed in these cases. It consists of jerky, irregular oscillations of the eyes in a horizontal plane when forcible closure of both lids is attempted. We have as yet no satisfactory explanation for the condition, although some writers believe it due to irritation of the sixth nerve nucleus.—ED.]

Although patients with peripheral paralysis protect themselves against a painful sensation caused by touching the cornea, nevertheless the usual lid closure (corneal reflex, p. 1062) either fails entirely or occurs very incompletely. On the contrary, automatic winking is retained. (See p. 1064.)

The true corneal reflex must not be confused (although the mistake is common) with the ordinary eye closure excited reflexly by the visual appreciation of an approaching object, even before the cornea has been touched. This latter is really an optico-facial reflex, *i. e.*, the optic nerve constitutes the sensory limb; and physiologically it is a most useful process, since it frequently protects the eye by closing the lid in time to prevent the injury, whereas the true corneal reflex would occur too late to be of any service. The optic reflex, like the genuine corneal reflex, is evidently either lost or diminished in peripheral facial paralysis. It is of some diagnostic importance in determining the condition of the facial in those cases where the true corneal reflex is absent as a result of anesthesia of the cornea (sensory trigeminal paralysis).

When a lesion is situated at *e*, the palate reflex may be lost. This can be recognized by tickling the patient's pharynx with a brush, although in unilateral facial paralysis it is often very difficult to be sure of it, as the paralyzed half is displaced toward the healthy half of the palate; in which case the displacement is often the only sign of the paralysis of the reflex.

Peculiar appearances of irritation are not infrequently observed in the partially paralyzed territory of old severe peripheral facial paralyzes which have recovered completely. These consist either of contractions, which may lead to the erroneous supposition of a facial paresis of the opposite side, or of associated movements and of fibrillary contractions in the paretic and atrophic territories.

¹ This is most readily observed when one tries to keep awake in the presence of others.

- Hitzig assumes that these phenomena depend upon a change in the irritability of the facial nucleus as a result of degenerative processes proceeding from the periphery, an hypothesis which coincides with Darkschewitsch's studies. The latter has discovered that peripheral lesions of the motor nerves lead to changes in the nuclear cells. These irritative phenomena in the facial territory may persist through life.

The electric irritability is generally altered in nucleoperipheral facial paralyses. In mild cases there is a more or less diminished excitability, and in severe cases a complete or partial reaction of degeneration, resulting in a degenerative atrophy of the paralyzed muscles. (See p. 1025.)

Severe peripheral facial paralyses commonly lead to vasomotor phenomena, as shown by the occurrence of coolness, cyanosis, and frequently some edema of the affected side. It has not yet been accurately determined whether this depends upon a connection between the peripheral facial and the vasomotor, or upon a lesion of the sympathetic fibers which are united to the facial branches in the periphery. Neither hypothesis is absolutely necessary, since the muscular action of the affected side is sufficiently impaired to produce some stasis (p. 1008 et seq.).

The *diminished sensibility of the affected half of the face*, not infrequently observed in facial paralysis, has led to various hypotheses. Some writers, contrary to the general opinion, assume that the facial contains some sensory fibers. This is, however, unnecessary in order to explain the disturbances of sensibility, for certainly sensory trigeminal fibers do anastomose at the periphery with the facial, and these may quite well be injured by the same cause. The absolute immobility of the affected half of the face and the associated circulatory disturbances are alone sufficient to dull the sensibility. Such disturbances are most frequently discovered while the muscles are being tested by the electric current; for this procedure is found to be more painful upon the healthy side, especially in severe paralysis, than upon the injured side. The observation certainly suggests that the degeneration of the muscles may alone be responsible for a disturbance of the sensory nerve terminations. In many cases an hysteric cause may explain the disturbance.

The *pains* accompanying rheumatic facial paralysis in the affected half of the face are probably due to coincident involvement of the peripheral trigeminal fibers running with the facial.

[At the Boston meeting of the American Neurological Association, 1906, J. Ramsay Hunt described a condition accompanying facial palsy which he considered the result of an herpetic inflammation of the geniculate ganglion. His very excellent description of this condition also contains the published cases in which herpetic vesicles had been considered coincidental. Hunt insists, however, that there is a definite syndrome, consisting of intense neuralgic pains in the ear, radiating over the face, tinnitus, vertigo, and frequently diminished hearing. An herpetic eruption soon appears on the concha, tragus, external auditory canal, or tympanic membrane; it is often very transitory and disappears rapidly, but is sometimes quite severe. At the outset there is usually a definite diminution in sensibility over the tympanic membrane and anterior surface of the external auditory canal, which, as a rule, lasts only a few days, and if the case be not seen early, will be missed or overlooked. The facial palsy which follows is of the peripheral type and generally very severe. Hunt believes that this condition establishes the fact that the seventh is a mixed nerve, and that its sensory part, which consists of the geniculate ganglion and the pars intermedia of Wrisberg, is distributed over the tympanum anterior wall of the external auditory canal and concha. The geniculate ganglion is ontogenetically the analogue of the Gasserian and spinal ganglia, and hence it is subject to the same conditions that govern herpetic inflammations elsewhere. The intimate connection of this ganglion by means of the petrosals with the auditory ganglion, Meckel's ganglion, the otic ganglion, and the Gasserian readily explain the vertigo, deafness, tinnitus, and pain radiations. A. S. Taylor and L. P. Clark presented a case at the meeting of the American Neurological Association, 1909, which seems to confirm Hunt's views, at least in part. The case was one of severe obstinate otalgia, which had been completely relieved by cutting the auditory, pars intermedia, and most of the facial nerve at the cranial opening of the Fallopian canal. The relief has been permanent thus far.]

(Almost two years.) His views on the peripheral sensory distribution, however, were not confirmed, since at no time subsequent to the operation were they able to demonstrate anesthesia of the concha, anterior wall of the external auditory canal, or tympanum.—Z.]

Bulbar paralysis, which, as has been already mentioned, includes a partial nuclear facial paralysis, sometimes causes an *increased salivary secretion*; and this is peculiar in as much as there is actually more saliva secreted than normally, and not merely an excessive flow on account of imperfect closure of the lips. We may assume that this increased secretion falls under the heading of a so-called paralytic secretion. Physiologists have noted it in animals after they have cut the several nerves leading to the submaxillary glands. Such an assumption seems permissible, because the fibers supplying the sublingual and submaxillary glands really come from the glossopharyngeal, which is also involved in bulbar paralysis. Against it is the fact that experimental paralytic secretion is rather a transitory condition, and even if continued, is never very decided. The more rational explanation seems to the author to be that the swallowing mechanism is affected in bulbar paralysis, the saliva accumulates in the mouth, and its presence reflexly stimulates the secretion.

(b) Spasms of the Facial

Spasms in the facial territory are not rare, but their description belongs to special pathology, so that here we need only mention their occurrence in tetanus, tetany, epilepsy, facial tic, and chorea. The peculiar twitching of the lid depending upon fibrillary contractions of the facial is of some diagnostic interest. It occurs in neurasthenics when they attempt to close the eyes at command. Such an attempt, as has been frequently noted, causes some degree of difficulty in many cases. This twitching is quite an important sign of neurasthenia. Irritative appearances in the territory of old facial paralyses have been mentioned in preceding paragraphs (p. 1076 et seq.).

EIGHTH CRANIAL NERVE; AUDITORY (*Acusticus*)

Paralysis of the Auditory Nerve

Auditory paralyses occur in diseases of the internal ear, of the petrous bone, in affections of the base of the brain and of the medulla oblongata, and finally as a part of cerebral hemianesthesias.

A unilateral acoustic paralysis in hemianesthesia is never absolute except in hysteric affections; there is more apt to be only a moderate impairment of hearing. This may be accounted for by the fact that the central innervation of the acoustic is not entirely crossed, and coincides with the fact that in unilateral lesions of the auditory center, situated in the temporal lobes, no instance of complete crossed deafness has as yet been observed. Whereas, Wernicke has shown that a bilateral lesion of the temporal lobes can produce bilateral deafness.

In examining the auditory nerve, a procedure which should, of course, be carried out in as quiet a room as possible, the perception of sound by air conduction must be sharply distinguished from that by bone conduction. In testing the former, a ticking watch or vibrating tuning-fork is held near the external auditory canal, the maximum distance determined at which one or both can be heard, and the two sides then compared. In testing the latter, the perception of sound by bone conduction, the watch or the shank of a tuning-fork is held upon the mastoid process, and any difference between the two sides determined from the patient's statements. Since neither watches nor tuning-forks emit sounds of definite intensity, Politzer¹ has constructed an acumeter with which a sound of constant intensity may be produced by allowing a small hammer to fall upon a metallic bar. Politzer's acumeter may be employed to test the perception not only of sounds transmitted

¹ Politzer, *Lehrb. der Ohrenheilkunde*, Stuttgart, 1887.

through the air, but also of sounds conducted by bone, in which case the instrument is brought into contact with the cranial bones by means of a rod-shaped attachment.

Rinne's test is also of some importance. It consists in holding a vibrating tuning-fork to the mastoid process, until the patient can no longer appreciate any sound; then the tuning-fork (which is still vibrating) is quickly approached to the external ear. If the auditory transmitting apparatus be functioning well, the tuning-fork is heard again (positive result of Rinne's test); should this not be the case (negative result of Rinne's test), there must exist some disease of this apparatus. If the test be positive, the transmitting apparatus is not necessarily perfect, because air conduction permits a better auditory impression than bone conduction, and slight affections of the sound-transmitting mechanism might escape notice.

To determine a disturbance of hearing independent of the otoscopic findings and Weber's and Schwabach's tests (see below), Rinne's test must be employed in a more exact quantitative manner, by determining the degree of superiority of air-conduction over bone-conduction, by measuring the time during which a vibrating tuning-fork is heard at the external auditory meatus after it has become inaudible upon the mastoid process. Under normal conditions this time for an A tuning-fork amounts to about thirty seconds. If Rinne's test give a negative result, we may proceed in the opposite manner, by determining the time during which the tuning-fork upon the mastoid process is heard after it has become inaudible when held in front of the external auditory meatus.

Zimmermann has recently objected to the principles involved in Rinne's test, believing that in placing the tuning-fork upon the bone we test the energy of movement of the handle of the fork, and that in holding the tuning-fork at the external auditory meatus we test the much greater energy of movement of the prongs. From this he concludes that the diagnostic importance of Rinne's test is doubtful and that the normal positive result cannot be employed as an argument for Helmholtz's theory, according to which the membrana tympani and the auditory ossicles are assumed to aid in the transmission of sound. According to Zimmermann's theory (see p. 1070 et seq.), the normal positive result of Rinne's test is due to the fact that the auditory ossicles may really be an accommodation mechanism for the acoustic organ, or, in other words, a sound-dulling, rather than a sound-transmitting, apparatus. These views of Zimmermann have been successfully combated by v. Bezold, who has suggested a new method of performing Rinne's test. Performed in this way, the test is free from objection and rehabilitates Helmholtz's theory. He provides the A tuning-fork with a rounded handle, and after the vibrations have become inaudible, both upon the mastoid process and at the external auditory meatus, he introduces this handle into the meatus, so that an air-tight closure of the canal is effected. It then becomes manifest that the audibility of the tuning-fork, introduced in this manner, is increased on the average by about twelve seconds over the ordinary perception by means of air-conduction; the vibrations are consequently perceived by air-conduction about thirty plus twelve seconds longer than by bone-conduction (the normal positive result of Rinne's test carried out in this manner). In this test air-conduction and bone-conduction are both measured with the handle of the fork, so that the results may be absolutely and directly compared.

The so-called *Weber's test* has a similar significance for the differentiation of impaired hearing due to disturbances of the conducting apparatus from that dependent upon affections of the nervous portion of the acoustic organ. The handle of a vibrating tuning-fork is placed upon the middle of the vertex, and the patient is required to state upon which side he perceives the louder sound. In affections of the conducting apparatus the sound is usually more distinctly perceived upon the affected side, because less energy is dissipated externally through the drum membrane, while the reverse is true in affections of the auditory

nerve or of the labyrinth. The chief objection to Weber's test is the uncertainty of the localization of the auditory perception in one ear.

Schwabach's test consists in determining whether the vibrating tuning-fork is perceived by bone-conduction for an abnormal period of time. If it be heard longer than normal, Schwabach supposes a disturbance of the conducting apparatus; if not so long as normal, an affection of the nervous mechanism. (The explanation is the same as in Weber's test.) If the investigator be possessed of normal hearing, this comparison is best made by removing the tuning-fork from the patient's mastoid process as soon as he declares it to be inaudible, and placing it upon the mastoid process of the investigator; the result is then to be compared with that obtained by reversing the process.

The results of all these tests, however, should be utilized with caution, since the pitch and intensity of the sound employed may sometimes cause them to vary and even be the direct opposite of what the formulated rules would lead us to expect.

The usual method adopted in ear clinics for testing the auditory nerve is to determine which of a series of tuning-forks, comprising the entire tone scale, can be appreciated. This method has not yet been adopted in internal medicine, because only gross disturbances can be utilized in the local diagnosis of cerebral diseases.

More recently, the reliability of this method has been questioned, because its theoretic basis (namely, that for the perception of the tuning-fork vibrations only the fundamental tones and no over tones come into consideration) seems to be inadequate. In spite of this, the method of testing with the tuning-fork series has given the practical and important result that in diseases of the middle ear a constant limitation of the tone perception is found in the lower scale; whereas in diseases of the internal ear and in old age, defects are found more commonly in the upper register.

Von Bezold¹ recommends, in place of the continuous series, one or two of the lower (weighted) forks (those which read the tones G₂ - - - - D₁ and D₁ - - - - A₁) and the use of the Galton whistle for the higher tones.

The acuity of hearing should be tested by means of the whispered voice, as well as by means of the above-described instrumental test. In a quiet room the examiner notes at what distance from each ear (the other being closed) the whispered voice can be heard; experience has shown that such a method frequently furnishes quite different results from the instrumental test. The whispered voice is preferable to the loud voice, not only because the latter would be too intense in a closed space, but also because the individual sounds and words are more uniformly adapted for auditory perception when whispered than when loudly spoken.

Irritative Phenomena of the Auditory Nerve

Subjective sound phenomena result from various cerebral diseases, from galvanic stimulation of the brain, and especially from affections of the internal and middle ear. The most familiar are the ear noises heard in chronic sclerotic otitis media, the "crux" of the otologists. This acoustic phenomenon of irritation does not possess in cerebral disease any very important local diagnostic significance, because even the most exact otoscopic examinations cannot differentiate with certainty the subjective perceptions of peripheral from those of central origin. A peripheral origin is much more probable, on the one hand, on account of the great frequency of middle-ear diseases, and, on the other hand, on account of the generally applicable law that the terminal organs of sensory nerves are the most irritable parts of the sensory apparatus. Pathologic appearances of the drum argue for a peripheral origin of the ear noises. A normal drum, however, does not necessarily exclude such an origin.

Auditory Vertigo (Ménière's Disease).—Since the vestibular branches of the acoustic nerve supply the semicircular canals, and since the latter are regarded as the organs of equilibrium, it is easy to understand that vertigo will result from affections of the acoustic nerve. Vertigo is, in fact, most commonly observed accompanying affections of the labyrinth and of the middle ear. (In regard to this, see chapter on Vertigo, p. 1092.)

Otoscopic Examinations

Disease of the auditory apparatus is frequent, even in people who consider themselves perfectly well. Hence, under all circumstances in

¹ Von Bezold, *Lehrb. der Ohrenheilkunde*, 1906.

which a disturbance of hearing has been determined, it is important to make an otoscopic examination. In no other way can we differentiate between disturbance of hearing dependent upon disease of the auditory nerve and that due to disease of the ear itself. This distinction, as was mentioned above, cannot always be determined by the Rinne test, even when conducted according to von Bezold (p. 1078). Weber's and Schwabach's tests (see p. 1079) also give at times uncertain results, and in some instances even an otoscopic examination fails, so that a disturbance of hearing will not always assist much in the diagnosis of cerebral disease.

The reader is advised to consult the otoscopic pictures in Politzer's *Atlas der Beleuchtungsbilder des Trommelfells*, Wien, Braumüller, 1896, and von Bezold's *Lehrbuch der Ohrenheilkunde*, Wiesbaden, Bergman, 1906.

Demonstration of Simulated Deafness¹

Simulation of total deafness of both ears may usually be detected merely by prolonged observation of the patient in a hospital.

The *simulation of bilateral or unilateral impairment of hearing* becomes evident when we test the patient's hearing (that of each ear) with his eyes closed, so that he cannot see the distance from which the sound comes. He will then express contradictory statements in regard to rapidly repeated tests.

Simulation of unilateral total deafness may be discovered in various ways:

1. The patient's normal ear is closed, and the examiner speaks directly in front of the supposedly deaf ear. If the patient claim not to hear this, either simulation or exaggeration exists, because under such conditions even the closed healthy ear would appreciate the conversational voice.

2. One end of a flexible rubber tube, about 4 feet long, is inserted into the external canal of the patient's ear; another similar tube into the other ear. Funnels are affixed to the other end of each tube. The examiner, speaking in a whisper behind the patient, talks at one moment into the one, and at another moment into the other, funnel, alternating as quickly as possible, and the patient is required to repeat what is said. In consequence of the confusion and the fatigue which this process produces, if simulation exists, the patient finally repeats what is spoken into the supposedly deaf ear. The examiner must be trained for the test. The best plan is to write down beforehand what is to be said in two columns, one marked L for the left ear, and the other R for the right ear. This procedure is to a certain extent analogous to the stereoscopic method of investigating simulated unilateral blindness (p. 1038).

3. An A tuning-fork is set in vibration and placed vertically upon the middle of the skull; if even one ear be normal, the patient must hear the tone. The test is then repeated with the normal ear closed, and if the patient says that he no longer hears the tone, it is evident that he is simulating, since by bone conduction the normal ear, even if it be closed, must hear the tuning-fork.

4. Many malingerers are exposed by the fact that they insist upon their inability to determine whether the tuning-fork vibrates or not,

¹ Partly taken from Siebermann, *Untersuchung auf Simulation von Schwerhörigkeit oder Taubheit*, Schweizerischer Medicinalkalender, 1895, p. 76 et seq.

when the examiner places a large vibrating tuning-fork (A or C or A) upon the skull in the neighborhood of the supposedly deaf ear, whereas the vibrations of such a type of tuning-fork can be felt even by the deaf.

Siebermann quite correctly calls attention to the danger of confusing exaggeration and complete simulation, and emphasizes the advisability of never placing any reliance upon the results of one method of examination.

In regard to the demonstration of the simulation of disturbances of hearing, the reader is referred to Burchardt's work, referred to upon p. 1039.

NINTH, TENTH, ELEVENTH CRANIAL NERVES: GLOSSOPHARYNGEAL, VAGUS, SPINAL ACCESSORY (VAGUS GROUP)

Physiology

These three nerves are so intimately connected at their origin in the oblongata, both during and after their exit from the jugular foramen, and they possess so many anastomoses, that experimental physiology has not yet succeeded in isolating the functions of each. This is especially so in the case of the vagus and spinal accessory. Clinical investigations are made exceptionally difficult, because, as a result of the anatomic relations of these nerves, pathologic conditions frequently affect the three simultaneously, both centrally and peripherally.

The *peripheral glossopharyngeal nerve* supplies *motor fibers* to the muscles of the pharynx, to the pharyngeal constrictors, and to the stylopharyngeus muscle; and it participates with the facial and the accessory in the supply of the muscles of the soft palate. In addition the glossopharyngeal is the *secretory nerve* of the parotid gland. From the petrous ganglion it gives off these secretory fibers through the tympanic nerve (Jacobson's) to the otic ganglion, and from there by means of the auriculotemporal nerve of the third trigeminal branch to the parotid gland (Fig. 422, p. 1073). The glossopharyngeal also contains *sensory fibers*, which are distributed to the back of the tongue, to the pharynx, and to the soft palate. These fibers convey impulses for the sensation of taste (*i. e.*, for bitter and sweet), and they also inhibit breathing during the act of swallowing.

The *peripheral vagus* includes both motor and sensory fibers. The *motor fibers*, together with those of the glossopharyngeal and accessory, supply the muscles of the pharynx, the soft palate, and the esophagus, so that the vagus, with the glossopharyngeal, plays an important part in the act of swallowing. In addition it furnishes motor fibers to the larynx through its inferior or recurrent laryngeal branch, and there supplies all the laryngeal muscles, except the cricothyroid and the two epiglottis muscles (the thyro- and aryteno-epiglottis). The last three, although not innervated by the recurrent laryngeal nerve, are supplied by fibers derived from the vagus, through the superior laryngeal nerve, which, therefore, innervates the cricothyroid muscles and the muscles of the epiglottis. The vagus is furthermore the motor nerve of the stomach and of part of the intestines; it is also the inhibitory nerve of the heart, for, as is well known, a centrifugal irritation of one or both vagi slows the action of the heart and at the same time diminishes the cardiac power, whereas sectioning one or both vagi increases the heart-rate. The vagus is further assumed to innervate the bronchial muscles and the vessels of the lungs. Sensory branches: It gives off a *small sensory branch* (auricular branch of the vagus) to the posterior wall of the external auditory canal. The mucous membrane of the pharynx, larynx, trachea, and bronchi is supplied by the vagus, as well as the heart and probably also the stomach and intestines. The sensory nerves for the upper part of the larynx run in the so-called *superior laryngeal branch*, those for the lower part of the larynx in the *inferior or recurrent laryngeal*. The sensory fibers of the vagus exert an important regulatory control over the breathing; their best-known effect is shown by centripetal stimulation of the superior laryngeal—the respiration ceases in the expiratory phase. The sensory vagus branches to the lung itself influence breathing to the extent that distention or inflation of the lung excites expiration, while compression or collapse of the lung excites inspiration. The automatic regulation of breathing, as explained by Hering and Breuer, should be understood to mean merely that by sensory irritation of the pulmonary branches of the vagus an

attempt is made to establish a median position of pulmonary distention, whereas the rhythm of breathing is independent of such regulation, being rather an automatic function of the respiratory center. In reality the only influence that the centripetal vagus fibers have upon the rhythm is that sectioning the vagus slows the respiration, while weak centripetal vagus irritation increases the rate. The vagus is the most important sensory nerve for coughing, which can be induced by any one of its sensory branches (even including the auricular branch). The vagus branch coming from the heart, which can be demonstrated in animals, is called the *Ludwig-Cyon depressor*. It is of some clinical interest, because its centripetal irritation produces a marked diminution of blood-pressure without affecting the heart, probably from vascular dilatation.

The peculiar sensation of nausea and the reflex vomiting depending upon such sensation may start from the sensory branches of the vagus to the pharynx and stomach. Vomiting does not, however, depend upon intact vagi, for in animals the vomiting paroxysm can still be excited from the stomach, even after bilateral section of the vagus. Other tracts for the vomiting reflex probably must exist, although they are unknown. The vagus is supposed to have some *secretory influence*, especially in the stomach, but it has not yet been definitely demonstrated.

The functions of the *peripheral spinal accessory nerve* are simple; they are purely motor. Its *internal branch* anastomoses with the pharyngeal branches of the vagus and the glossopharyngeal, thus sharing in the motor innervation of the soft palate, while its *external branch* supplies the sternocleidomastoid and trapezius muscles.

The determination of the central origin of fibers which control individual functions is much more difficult than the study of the peripheral branching and functions of these three nerves. Two points are sure—that the taste-fibers are derived from the glossopharyngeal nucleus, and that the innervation of the sternocleidomastoid is exclusively a function of the accessory nucleus. From reasons which have been detailed above (p. 1081), we are still undecided whether many functions executed in the peripheral tracts of the vagus and glossopharyngeal are not controlled by fibers which in reality are derived from the accessory nucleus, but which at the periphery are associated with the two other nerves. For instance, the heart-accelerating fibers of the vagus, and especially the motor fibers for the larynx, are supposed by many writers to be derived from the accessory nucleus. Grabower, however, has recently denied this relation of the accessory to the larynx. At all events the question is not settled. Nor is it yet possible to state with certainty how far the accessory nucleus shares in the innervation of the glossopharyngeal and vagus fibers which supply the swallowing and palate musculature.

In regard to the anatomic relations of the nuclei of the three nerves of the vagus group, see Figs. 430 and 431.

Pathologic Relations

The fibers of the three nerves of the vagus group may be affected either in their peripheral course or within the cranium, *i. e.*, in the medulla oblongata. The same peculiarities are true in regard to their central (supranuclear) innervation, as in the case of the nerves to the ocular muscles, of the motor trigeminus, and of the superior branch of the facial, *viz.*: that their central innervation is not exclusively contralateral, but that the hemisphere of each side takes part in innervating the two nerves. (See Fig. 403, p. 1041.) As a result, lesion of one hemisphere occasions very little or no disturbance in the nerves of the vagus group, because the other hemisphere then performs the function sufficiently well; and, therefore, without further discussion unilateral affections can, for the most part, be attributed to a lesion at the base of the brain or in the oblongata, provided, of course, that the trouble is situated within the skull. This is exactly the same condition as in unilateral paralysis of the eye muscles (see p. 1040 et seq.) and motor paralysis of the trigeminus (p. 1061). With a cerebral hemiplegia, such as is usually localized in the cerebrum, there is practically never any disturbance of the vocal cords, of the muscles of swallowing, nor of the sternocleidomastoid, whereas a paresis of the trapezius is regularly noticed upon the

hemiplegic side, because the innervation of this muscle is, for the most part, crossed. The clavicular portion of the trapezius, however, which aids in respiration, is bilaterally innervated and so exempt from this paresis. A bilateral paralysis of the nerves of the vagus group may, of course, originate from bilateral hemisphere lesions as a "pseudobulbar" condition. (See p. 1090.)

Symptomatology of Lesions of the Three Nerves of the Vagus Group.—Disturbances of the motor innervation of the soft palate may occur in paralysis not only of the facial, but also of the glossopharyngeal and vagus, as well as of the nuclear and trunk portions of the accessory, and, according to p. 1061, of the motor trigeminus. In regard to the phenomena of unilateral or bilateral paralysis of the palate, see the section upon the facial nerve (see pp. 1063 and (reflex) 1075), and p. 1062 in regard to the influence of the trigeminus. In a similar way the peripheral glossopharyngeal and vagus, and even the region of origin of the accessory, are to be considered in connection with the other movements of swallowing. A patient's subjective complaints and the examiner's observation of the act of swallowing, will disclose any affection of that function. A unilateral vagus paralysis, such as is observed after injury, does not noticeably affect swallowing. Disturbances in the motor innervation of the larynx, proceeding from the vagus or the accessory, become evident either during phonation, or by the exhibition of deficient laryngeal closure or laryngeal stenosis (in posticus paralysis, see below). Imperfections in phonation depend upon a lesion of fibers running to the vocal cord musculature in the inferior laryngeal nerve. Deficient closure of the glottis depends upon a paralysis of the glottis constrictors (crico-arytenoideus lateralis and inter-arytenoidei), as well as of the aryteno-epiglottis. The two former are supplied by the inferior laryngeal and the latter by the superior laryngeal nerve. The consequence of deficient laryngeal closure is that patients readily choke in swallowing, and can no longer effectually cough or strain. Traube has proved that paralysis of the glottis closure, with inability to cough and expectorate, is the most essential cause of the disastrous results (vagus pneumonia) of bilateral section of the vagus in animals and of bilateral vagus paralysis in men. Whether or not paralysis of the bronchial muscles and of the pulmonary vessels plays any rôle in this is not yet accurately determined. In unilateral vagus paralysis phonation and glottis closure are not always so markedly affected as one would think, because a more pronounced movement of the healthy vocal cord will, to a great extent, compensate for the paralyzed cord. Still, the hoarse, feeble voice of complete unilateral vocal paralysis is so very characteristic that such a diagnosis may sometimes be made, even before a laryngoscopic examination, providing the other clinical symptoms suggest it. A gradually developing paralysis of the recurrent nerve (whether this be of peripheral or of nuclear origin) almost always involves the crico-arytenoideus posticus first. This muscle widens the glottis. Hence, the earliest symptoms of an increasing motor laryngeal paralysis is a narrowing of the glottis, because the constrictors overpower the weakened posticus. The corresponding vocal cord assumes a position of adduction. Should the paralysis be bilateral, there may result a serious obstacle to breathing, with all the symptoms of laryngeal stenotic dyspnea (see p. 93 et seq.), even necessitating tracheotomy. Such a condition is generally described briefly as "posticus paralysis."

This remarkable selection of the crico-arytenoideus posticus in the beginning of recurrent paralysis has led to countless discussions. No satisfactory explanation has yet been given. One theory is that those neurons which preside over glottis widening suffer on account of a greater sensitiveness, but this seems to the author arbitrary and superfluous. A much simpler explanation is that, quantitatively, the musculature of the glottis constrictors overpowers the dilators very decidedly. This preponderance is in keeping with the fact that in phonation, coughing, straining, and, in short, in all forms of glottis closure, the constrictors accomplish very much more than the dilators. As a matter of fact, all laryngeal muscles, with the single exception of the crico-arytenoideus posticus, subserve the function of narrowing the glottis, and, therefore, it is not surprising that this muscle is the first to suffer, and that in partial laryngeal paralysis the constrictors overpower it. Evidently, as the paralysis increases, the narrowing of the glottis becomes less marked, while the vocal cord (or cords) from a position of adduction assume more and more the so-called cadaveric position. (See Fig. 341, p. 900.) The exact diagnosis of a motor laryngeal paralysis can only be made with the help of the laryngoscope. (See the chapter upon Laryngoscopy and the illustrations of the larynx reproduced there, p. 900.) A normal laryngoscopic picture is characteristic of hysteric aphonia: the larynx resembles that of a person voluntarily whispering. There is no actual paralysis in the territory of the vagus and accessory, but merely a psychic inability to control the speech. Spasm of the glottis and the spastic form of hysteric aphonia may be mentioned here, as motor vagus accessory symptoms; but for their explanation the literature of special pathology should be consulted.

See p. 1062 et seq. (trigeminus) concerning derangements of taste peculiar to lesions of the glossopharyngeal (especially for bitter and sweet). Affections of the sensory innervation of the larynx (superior and inferior laryngeal nerves) can be demonstrated by touching the mucous membrane of the larynx by means of a curved laryngeal sound, under the guidance of a mirror, and noting the absence of sensitiveness, and even the loss of the cough reflex.

The determination of disturbances in function of the cardiac and pulmonary branches of the vagus is usually very difficult, because all the circulatory and respiratory changes produced by irritation and paralysis of this nerve may arise pathologically in other ways, especially in affections of the heart and of the lungs themselves, and also reflexly from almost any nerve territory. The establishment of less ambiguous symptoms, especially the determination of the phenomena described above in connection with the act of swallowing and the laryngeal innervation, as well as the establishment of lesions whose nature and position can be definitely attributed to the vagus, will generally be sufficient to attribute certain respiratory and circulatory disorders to paralytic or irritative vagus phenomena. The cases of traumatic vagus paralysis are the easiest to understand.

The results of surgical or other accidents, such as cutting the vagus nerve during operations, or the results of injury to both vagi from the pressure of tumors, prove that a unilateral vagus paralysis need not influence the pulse very materially. At first it may be accelerated, but later on it will become equalized. A double vagus paralysis will, however, generally induce a permanent acceleration, up to 160 beats in a

minute. Dilatation of the heart has not yet been observed as a result of unilateral or bilateral vagus paralysis; nor is there any foundation for the frequent assumption that irregularity of the pulse is to be attributed to paralyzing affections of the vagus. On the contrary, physiology teaches that irritation of the vagus may cause irregularity in the pulse.

The rule formulated by Gerhardt in connection with the diagnosis of the cause of *tachycardia* should be mentioned here: "Taken all in all, the majority of nervous tachycardias are to be attributed to vagus paralysis, those with very rapid pulse (above 200) to a combination of vagus paralysis with sympathetic irritation, a few rather milder forms to the latter alone." Martius adds: "This rule coincides with well-known physiologic facts. In unpoisoned animals an acceleration of the heart rate of 30 to 70 per cent. (not more, Aubert) can be brought about by stimulating the accelerating nerve of the sympathetic. After bilateral sectioning of the vagus, the acceleration of the pulse-frequency in mammals is not very great. According to von Bezold it may rise to 120 to 180 beats. The following conclusions may be drawn: Acceleration up to about 120 beats (30 to 70 per cent.) depends upon irritation of the sympathetic; from 120 to 180 beats, upon paralysis of the vagus; more than that, upon a combined action of both causes."¹ Nothnagel has also made an attempt to formulate rules for diagnosing the cause of tachycardia. He says: (1) "If a very decided acceleration of the pulse occur in paroxysmal tachycardia, if the rhythm be quite regular, and the cardiac impulse very weak, if other symptoms be either absent or only develop as consequences of incomplete systoles, if, finally, the paralysis of other nerve-tracts accompanying the vagus can be confirmed at the same time, then one can assume a vagus paralysis as a cause in this special case. (2) If during the attacks of tachycardia the cardiac impulses be vigorous, if the peripheral arteries be well filled, and the tension be preserved (but this is not in any sense a necessity), if other marked evidence of irritation in vasomotor nerve-tracts appear in paroxysms, then the assumption of a condition of irritation of the accelerating nerve (sympathetic) is justified."

Martius objects to the assumption of a vagus paralysis or of a sympathetic irritation to explain tachycardia. He assumes neither a vagus paralysis nor sympathetic irritation to interpret the characteristic clinical picture of paroxysmal tachycardia, but considers that it depends upon a temporary acute cardiac insufficiency with dilatation, in which the tachycardia is one of the secondary, or probably compensatory, symptoms. But this conception of Martius does not seem logical to the author; for in paroxysmal tachycardia evidence of cardiac insufficiency is so insignificant that in some cases one might better assume a sort of epileptic discharge in the territory of the accelerating nerve of the heart, which exert positive chronotropic influences (Engelman); and in others, on the contrary, the clinical picture of paroxysmal tachycardia apparently depends upon an accumulation of regular extrasystoles (p. 111).

The statements which are to be found in literature concerning the behavior of the breathing in vagus paralysis are of little use. According to physiologic experiments, it is fair to assume here, as with the heart, that only bilateral lesions can cause serious difficulties. Edinger's statement that vagus paralysis may be associated with pulmonary distention, and consequently with dyspnea, is worth noting. Vagus pneumonia (as we saw upon p. 1083) depends essentially upon incomplete laryngeal closure, and is, therefore, merely an indirect pulmonary symptom of vagus paralysis.

As yet there is very little known about the effect of vagus paralysis upon disturbances of the functions of the stomach and intestines in man. This alone appears certain—a unilateral vagus paralysis does not noticeably influence these functions.

We now come to the mention of the symptomatology of the affections of the so-called external branch of the accessory, which supplies

¹ Martius, *Tachycardia*, Stuttgart, Enke, 1895.

the sternocleidomastoid and trapezius muscles. A unilateral paralysis of the sternocleidomastoid causes a moderate twisting of the head toward the paralyzed side, associated with a slight elevation of the chin, due to the action of the antagonists. Turning the head to the healthy side, although performed less vigorously than normally, is not prevented, because this movement is accomplished not exclusively by the sternocleidomastoid, but also by the deep muscles of the neck, especially the obliquus capitis inferior, and the splenius of the other side. The clonic and tonic wry neck (*tic rotatoire, caput obstipum spasticum*) depend partly upon a unilateral irritation of the spinal accessory nerve supplying the sternocleidomastoid. Yet the unsatisfactory results following myotomies of the sternocleidomastoid alone, and the very much better results when the opposed splenius and the oblique capitis inferior have also been cut, show that the name "accessory cramp" for this condition is not absolutely justified. In reality the condition depends much more upon spasm of an extensive central area which supplies functionally related muscles. This corresponds to the modern conception of tics that they are automatisms which are developed from coördinated voluntary movements. The symptoms of unilateral paralysis of the trapezius vary according to whether the entire muscle or only separate portions of it are involved. If complete, the affected shoulder hangs lower; the shoulder-blade is thrust out obliquely forward and outward, and its inner border runs obliquely from below upward and outward. The power to lift the arm is somewhat impaired, but not nearly so markedly as in serratus paralysis. If only the central portion (acromial) be paralyzed, the upper half of the median edge of the shoulder-blade is depressed outward (*mouvement de bascule, Duchenne*). According to Schlodtmann, if the origin of the accessory be affected, this central portion of the muscle remains exempt, because it is entirely or partly supplied by the cervical plexus. This point has not yet been definitely decided, nor has the extent to which the cervical nerves assist in the innervation of other parts of the trapezius. It is worth noting that in juvenile muscular atrophy the clavicular bundle of the trapezius, whose function is essentially respiratory, remains intact longest, so that Duchenne has described it as the ultimum moriens of the muscle. In regard to the analogous behavior of this portion in hemiplegia, because of its bilateral innervation, see p. 1083.

TWELFTH CRANIAL NERVE: HYPOGLOSSUS

The hypoglossus is the motor nerve of the tongue, and, therefore, aids in chewing, swallowing, and especially in speaking. Its function is tested by observing whether coarse movements of the tongue are performed equally well upon both sides, and by watching the patient while chewing and swallowing. With a unilateral hypoglossal paralysis or paresis, the tongue, when protruded, deviates toward the paralyzed side, because the healthy genioglossus muscle overpowers its paralyzed fellow. If the action of the genioglossus be lost or impaired, the protruding action of the genioglossus of the opposite side preponderates, and the tip of the tongue deviates toward the paralyzed side.

Further evidence proving that the genioglossus muscle is at fault is furnished by observing the tongue as it rests naturally upon the floor of the mouth in unilateral hypoglossal paralysis. As a result of the greater strength of the unaffected muscle,

the tip will, in this position, be deviated toward the healthy side; and, in addition, a more prominent arching of the dorsum of the tongue will be noted upon the paralyzed side. This curving shows that the forward pull of the genioglossus has ceased.

In unilateral hypoglossal paralysis we by no means always notice any pronounced disturbance either by chewing or swallowing. Even articulation may be carried out reasonably well, especially after some practice.

In old peripheral paralyses of the hypoglossus the affected half of the tongue is flaccid, thin, and wrinkled, and often shows fibrillary contractions in the shape of peculiar peristaltic wavering. Electric stimulation of the lingual nerve (chorda tympani fibers) will oftentimes intensify this wavering so decidedly that an actual movement of the tongue occurs (pseudomotor action, Heidenhain). The tongue is frequently more coated upon the paralyzed than upon the healthy side.

With bilateral hypoglossal paralysis the disturbances of function are naturally very marked. The tongue lies flaccid upon the floor of the mouth, and can be protruded only very incompletely, if at all. Speech becomes incomprehensible, and mastication, chewing, and swallowing finally become impossible. The patient cannot even swallow the saliva, but must either spit it out frequently or drool constantly.

In a peripheral hypoglossal paralysis the muscles attached to the hyoid bone and supplied by the descending branch of the hypoglossus are also frequently involved together (sternothyroid, thyrohyoid, sternohyoid, and the inferior belly of the omohyoid). The fibers for these muscles originate in the second and third cervical nerve-roots. Part of them join the root of the hypoglossal nerve and later leave it again as the descending branch; part of them join the latter branch further down. When in conjunction with a lingual paralysis, these muscles are found to be affected, it is natural to conclude that the lesion is situated in the hypoglossal trunk below the anastomosis with the superior cervical nerves. The paralysis of the inferior hyoid muscles can be recognized by an atrophy of the musculature over the thyroid cartilage, and by a more noticeable prominence of the latter. If the paralysis be unilateral, the larynx will be seen to be dislocated laterally during the act of swallowing. Under some circumstances such paralysis may be demonstrated by an electric examination (motor points, see p. 1013, Fig. 390).

The electric examination of the tongue itself should be carried out in the ordinary way (p. 1009 et seq.). The motor point of the hypoglossus is situated just behind and above the cornu of the hyoid bone. (See p. 1013, Fig. 390.) In many individuals the nerve can be stimulated alone at this point by deep pressure of the fine electrode.

The hypoglossus of each side is innervated by both hemispheres, and, therefore, unilateral cerebral lesions causing a hemiplegia give very little evidence of hypoglossal paralysis. The same conditions apply as in the behavior of the superior facial branch in hemiplegia of or in central facial paralysis. (See p. 1066 et seq.) The crossed influence is, however, responsible for a more or less plain deviation of the tongue toward the paralyzed side in an ordinary hemiplegia, depending, as has already been said, upon a weakness of the genioglossus muscle upon the paralyzed side. This deviation of the tongue in hemiplegia ordinarily runs a parallel course with the facial paralysis, and for this reason was formerly attributed to the facial nerve. Such a supposition is, of course, incorrect. The coincidence of central facial paralysis and hypoglossal paresis depends upon the intimate proximity of the central tracts, or even of the cortical centers, of these two nerves.

Ordinarily, no particular difficulty in chewing, swallowing, or speaking results from this hemiplegic hypoglossus paresis; at most it has only a transitory effect on these functions.

II. THE CHARACTERISTICS OF MOTOR HEMIPLEGIA; PSEUDOBULBAR SYMPTOMS

In the preceding paragraphs (see the diagram, Fig. 403, p. 1041) we have emphasized the fact that most of the cranial nerves are supplied by both hemispheres, so that a unilateral hemispheric lesion producing a hemiplegia of the extremities does not cause any marked crossed paralysis of the cranial nerves. This rule applies particularly to the nerves of the eye muscles (except in the conjugate tract for the lateral movement), to the motor trigeminus, to the motor glossopharyngeal, to the vagus, and to most fibers of the accessory, *i. e.*, those to the vocal cords and to the sternocleidomastoid. As was mentioned above, a unilateral hemispheric lesion has a slight crossed effect upon the upper branches of the facial, upon the hypoglossal (genioglossus) and upon the fibers to the trapezius, with the exception of those to the clavicular portion, which remain intact. The fibers of the inferior facial branch are, on the contrary, very decidedly affected, because crossed. Therefore, the typical clinical picture of cerebral hemiplegia includes a pronounced paralysis of the muscles supplied by the lower branch of the facial, while those supplied by the other motor cranial nerves are either intact or slightly and partially paralyzed.

In a similar way the respiratory and abdominal muscles, apparently innervated bilaterally, present merely a slight negligible weakness on the paralyzed side.

A bilateral defective innervation is, however, probably present in any unilateral hemispheric lesion, but escapes notice because it is very difficult to detect any objective evidence of a moderate degree of bilateral paralysis (this was alluded to in the case of the eye muscles upon p. 1041 *et seq.*, and is quite as true for other muscle territories innervated bilaterally).

Wernicke¹ and Mann undertook not long ago a more accurate analysis of motor hemiplegia in order to compare the degree of involvement of the individual muscles of the extremities. They demonstrated, what had been well known for a long time, that the leg is always affected less than the arm, and proximal less than distal parts, and formulated the following rules in regard to the amount of involvement of the individual muscle groups of the arm and leg.

Arm.—The movements most affected, and in milder and less distinctive paralysis oftentimes the only ones, are extension in all joints (elbow, hand, and finger joints), supination of the hand, abduction and adduction, and the opposition of the thumb, and spreading of the fingers. All other movements, especially those of flexion, are less affected. The ordinary position of the paralyzed arm is, therefore, flexed at all joints and slightly pronated.

*Leg.*²—The muscles most decidedly paralyzed, and, in milder and less distinctive paralysis, the only ones affected, are those which shorten and advance the leg in walking, *i. e.*, those which flex the leg and are thereby efficient at the first stage of the movement. The more important muscles for walking, those which elongate the leg and so push the body forward, are, on the contrary, either less paralyzed or in milder cases not at all affected. The flexors of the thighs and legs, the iliopsoas, the gracilis, the sartorius, and the dorsal flexors of the foot, *i. e.*, the tibialis anticus and extensor digitorum communis, are, therefore, conspicuously paralyzed. Although the long head of the biceps and the semitendinosus and semimembranosus can act as flexors of the leg, they are less paralyzed. This, however, does not argue against the above rule, because, on account of their extensor action upon the hip-joint in walking, they functionate not as flexors of the leg, but as extensors of the thigh; in other words, as elongators of the leg. In the same way the gastrocnemius does not act as a flexor of the leg in walking, but as an extensor of the foot, therefore, elongating the leg, and so, in accordance with the above rule, remains comparatively free in hemiplegias. It may be added that in hemiplegias, flexion of the thigh is often found to be less affected than Mann's rules would lead us to think, because the quadriceps, acting as an extensor, aids the iliopsoas in this movement.

¹ Wernicke, Berlin. klin. Woch., 1889, p. 45, and Lehrb. der Gehirnkrankheiten, Cassel, Fischer, 1881.

² Mann, Volkmann's Sammlung klin. Vorträge, Neue Folge, Leipzig, 1895, No. 132, and Deut. Zeit. f. Nervenheilk., 1896, vol. x, parts 1 and 2, p. 1.

To explain this peculiarity in distribution of motor paralysis in hemiplegias, which applies both to cerebral and to spinal types (see p. 1125), we may assume that the seriously paralyzed muscles, like the muscles supplied by the inferior branch of the facial, depend for their innervation upon the opposite hemisphere, whereas the groups of muscles less affected by the hemiplegia, like those supplied by the upper branch of the facial and most motor cranial nerves, are supplied by both sides, and, therefore, exhibit perhaps a weakness, but never any decided paralysis. The researches of Pitres and Dignat¹ completely corroborate this assumption of bilateral innervation, for in cerebral hemiplegias they found a diminution in the power of the healthy leg amounting to 50 per cent, in the healthy arm amounting to 38 per cent. Therefore, what we call hemiplegias are not hemiplegias at all, accurately speaking, but paraplegias with a preponderating crossed paralysis.

Fig. 423.—Left hemiplegia, showing contractures and distortion of mouth (Dr. E. G. Cutler, Massachusetts General Hospital).

The rules proposed by Mann in regard to the behavior of the elongators and shorteners of the leg frequently apply in spinal cord lesions which partially interrupt the motor conduction upon both sides (incomplete transverse lesions, motor systemic diseases). Perhaps this peculiarity may be explained by assuming that, in addition to their bilateral innervation, the elongators possess other more favorable conditions of innervation, *e. g.*, possibly a greater number of fibers in their conduction tracts, or increased capacity. If we assume that this peculiarity of bilateral innervation of muscle groups applies to the peripheral neurons also, it would signify a better innervation of the spinal reflexes, or a better tonus of these muscle groups. This, together with the explanation given on p. 954, would account for the fact that the slightly paralyzed and probably bilaterally innervated muscle groups (in the arm the flexors, in the leg the extensors) preponderate in hemiplegic contractures.

¹ Cited by Pierre Marie, *Leçons sur les maladies de la moelle*, 1892, p. 26.

In bilateral hemispheric lesions we observe very characteristic appearances upon the part of the motor cranial nerves, as a result of their bilateral innervation. Since each lesion affects fibers for both sides, a bilateral deficiency of innervation must result, for which there can be no compensation. A glance at Fig. 403, p. 1041 (supposing a coincident existence of lesions x and z), will make this clear. If these bilateral hemispheric areas involve especially the motor fibers, they may, by combination, cause a marked bilateral paralysis of those motor cranial nerves which would not be conspicuously paralyzed were the trouble unilateral. Since bulbar nerves (like the motor trigeminus, accessory, hypoglossus, and upper branch of the facial) are affected, the clinical picture will closely simulate the paralyzes originating in the nuclear regions of the oblongata and the pons. The symptoms of this combination of hemiplegias are, therefore, spoken of as *pseudobulbar symptoms*. Pseudobulbar symptoms may be occasioned either by two hemispheric lesions coming on simultaneously, or by the addition of a fresh lesion of one hemisphere to an old hemiplegic lesion of the other side. The latter has destroyed the fibers of the hemisphere corresponding to the nerves in question, but for well-known reasons has caused no symptoms.

Similarly, in complete conformity with the theory of bilateral innervation, experience teaches that as soon as a hemiplegia of the other side is added to the first hemiplegia of patients who have retained but slight residual effects of such a hemiplegia, the side first affected promptly becomes more seriously paralyzed, because the compensatory influence of the other hemisphere now disappears.

III. CEREBRAL SENSORY DISTURBANCES

The sensory tract in the brain may be involved in a number of entirely different locations, as a clinical result of which there will be a more or less distinct unilateral disturbance of sensation. A portion of the cerebral sensory tract, however, is so fused that a circumscribed lesion producing marked sensory disturbances can be situated only in certain locations. These places are found exclusively in the compact portion of the sensory tract which is formed by the fillet. The sensory fibers of the fillet arise from the nucleus gracilis and nucleus cuneatus in the medulla, partly cross to the opposite side, in the so-called decussation of the fillet, run through the tegmentum of the crus cerebri to the ventral nucleus of the optic thalamus. From this point they are connected with the parietal lobe and the motor region by means of the thalamic radiations which pass through the posterior part of the posterior limb of the internal capsule.¹ (See Fig. 428.)

Hemianesthesia may consequently be observed as the result of lesions: in the posterior columns of the medulla; in the pons if the region of the fillet be affected; in the tegmentum of the crus, when the lesion is situated between the red nucleus and the substantia nigra; in the subthalamic region and the adjacent posterior portion of the internal capsule (see Fig. 428); in the fibers of the corona radiata proceeding from the optic thalamus; and in extensive lesions of the parietal lobe, particularly when they involve the inferior parietal lobule, and of the central convolutions.

Cerebral hemianesthesia is most frequently dependent upon a lesion in the posterior portion of the internal capsule. Milder degrees of sensory disturbances may originate in the most varied locations in the brain, dependent upon the diffusion of that portion of the sensory tract which is not contained in the fillet, but very little is known about them.

The Character of Cerebral Hemianesthesia Produced by Anatomic Lesions, and Its Differentiation from Hysteric Hemianesthesia and Spinal Hemianesthesia.—The cerebral hemianesthesia due to anatomic causes is characterized by the fact that it involves the spinal sensory tracts, together with the cutaneous area supplied by the trifacial; in some cases the optic tract may also be involved, and, in rare instances, the acoustic tract. Involvement of the optic tract occurs when the lesion affects the sensory fibers in the region of the posterior portion of the internal capsule, or those in the corona radiata of the optic thalamus, when it involves the optic radiation (see Fig. 428, p. 1099), passing near the subthalamic region from the primary optic centers, *i. e.*, the pulvinar and external geniculate body to the cerebral cortex, or when it implicates the primary optic centers themselves. The

¹ The cerebral course of the sensory fibers from the anterolateral columns of the cord (see Fig. 455, and Fig. 456, p. 1142), which in physiologic and pathologic importance are second only to those of the posterior columns, is as yet unknown. Clinical experience would lead us to suppose that at least some of these fibers become associated with those of the fillet.

acoustic tract is affected when the lesion involves the internal geniculate body and posterior corpus quadrigeminum, or the acoustic radiations (see Fig. 428, p. 1099), which connect these structures with the temporal lobe. Visual disturbances in cerebral hemianesthesia dependent upon anatomic causes are always hemiopic in character, since the visual center is cut off from the retinal halves corresponding to the side of the lesion. Hearing is simply impaired and never abolished upon the side opposite to the lesion, since each acoustic nerve is connected with both temporal lobes. (See diagram, Fig. 403, p. 1041). Smell and taste are always retained, because the lesion is at some distance from the olfactory and gustatory fibers. These fibers from each side are connected with both hemispheres and do not run in a compact bundle, so that they cannot easily be destroyed by a circumscribed lesion. Cerebral hemianesthesia is further characterized by the fact that all the sensory powers may be involved—touch, pressure, pain, temperature, bone-sensation, the perception of the position and of passive motions of the extremities, and stereognostic sense, although they are usually very incompletely affected. The perception of the position and of passive motions of the extremities and the stereognostic recognition of objects are most affected and may be completely abolished, while the sensations of touch, pain, and temperature are usually simply diminished. The disturbance is most marked at the distal ends of the extremities, possibly because this region is supplied by a comparatively larger number of crossed fibers from the opposite hemisphere, while the proximal portions of the extremities are presumably supplied by fibers from both hemispheres. If the cause of the hemianesthesia be situated in the pons or in the uppermost portion of the medulla, a so-called alternating hemianesthesia may be produced, since the sensory trigeminus is involved below its decussation and is paralyzed upon the side opposite to the anesthetic extremities. The hemianesthesia frequently extends somewhat beyond the median line of the body, because the cutaneous terminations of the peripheral sensory fibers overlap the median line.

Since the cerebral hemianesthesia is crossed, *i. e.*, situated upon the side opposite to the lesion, it must be assumed that the sensations for one-half of the body are received, for the most part, by the opposite half of the brain. Since a triple decussation is improbable, we are led to suppose that the cerebral decussation (occurring chiefly in the decussation of the fillet) involves only those fibers which do not decussate at lower levels. (See Fig. 448.) This fact explains why the complicated conditions of spinal hemianesthesia (see p. 1125 *et seq.*) are absent in hemianesthesia of a cerebral type.

Hysteric hemianesthesia differs from anatomic cerebral hemianesthesia in the fact that, together with the different qualities of sensibility of the skin and more deeply situated organs (at times even the bones), including the distribution of the trigeminus, the higher senses are usually involved, not only sight and hearing, as may be the case with a cerebral lesion, but also smell and taste. The visual disturbance is amblyopic rather than hemiopic, and consists of diminished sharpness of vision, together with narrowing and pathologic fatigue weakness of the visual field upon the hemianesthetic side. The auditory phenomena may consist of a complete unilateral deafness, which does not occur in anatomic cerebral hemianesthesia. It must, nevertheless, be noted that the higher senses may not be involved in hysteric hemianesthesia. It is rather characteristic of this form of hemianesthesia that the most markedly disturbed sensation is that of pain. In regard to the variations in the sense of muscular contraction in hysteric disturbances of sensation and those of anatomic origin, see p. 952.

Sensory Disturbances with Cortical Lesions.—Sensory disturbances with cortical lesions require particular consideration, since there is a conflict of views in reference to this subject. As the sensory terminals extend over a very large cortical area and are more diffused than the terminals of the motor tract, it is apparent that a localized cortical lesion can produce only a partial disturbance of sensation. These sensory disturbances are most marked in lesions situated in the so-called motor region and in lesions of the parietal lobes. These areas receive the termination of the thalamic radiation which conducts the fibers of the fillet to the cortex. It is likely that sensory fibers of different qualities terminate heterogeneously in both these areas, and that the location and extent of the pathologic lesion is indicated by the degree rather than by the nature of the sensory disturbance. The character of the sensory disturbances in lesions of the so-called motor area has a special practical interest, since such disturbances play an important, though still somewhat uncertain, rôle in the localization of these lesions. In the first place, it should be noted that sensory disturbances are not constantly observed with lesions of the motor area. From what has previously been said, we are led to

suppose that they are absent when the lesion is quite circumscribed. In extensive lesions of the motor area, however, the motor symptoms are usually accompanied by sensory disturbances. They are almost always most pronounced and sometimes present exclusively in the distal portions of the extremities, particularly in the terminal phalanges of the fingers. This peculiarity, which has been previously referred to as characteristic of cerebral hemianesthesia caused by a more deeply situated lesion (p. 1090), is probably due to the fact that the proximal portions of the extremities send sensory fibers to both hemispheres. It is well known that the analogous statement is true in reference to motor disturbances. (See p. 1088.) A further characteristic of cortical disturbances of sensation is that they affect those sensory functions which are dependent upon the correlation of sensory impulses, rather than the individual qualities of sensation themselves. The sensations for pain, touch, and temperature are usually but slightly if at all affected, while there are distinct disturbances of the stereognostic sense, of the perception of the position, and of the passive movements of the extremities, as well as impaired localization of the sensations of touch and pain.

This is perfectly clear in regard to the stereognostic sense and the perception of the position and passive movements of the extremities, because it is only after the individual sensations reach the cortex that they are elaborated as such. The same must also be true of the localization of sensations; for, although it is primarily dependent upon the individual conduction of sensory impressions, the realization of these sensations in the cortex for localization purposes is a complicated function of deduction, which is accomplished through the association pathways. Confirmation of this is obtained by the clinical observation that localization of sensations may be destroyed, although its elementary sensations themselves are fairly well preserved.

IV. VERTIGO

Vertigo is a peculiar pathologic phenomenon which plays a great rôle in neuropathology, and is characterized clinically by a feeling of uncertainty as to the position of the body in space. With this there is physiologically associated the discomfort attendant upon disturbed equilibrium; in severe cases there are also motor disturbances of equilibrium. Other physiologic sequelæ of vertigo are the apparent movement of objects,¹ due chiefly to disturbance of visual perceptions (*rotary vertigo*) and affections of other sensory perceptions, particularly of the sensation of contact between the soles of the feet and the floor (apparent undulation of the floor). More remote sequelæ, produced by reflex action, are nausea and vomiting, a sense of faintness, palpitation, and even loss of consciousness.

The Pathogenesis and Clinical Significance of Vertigo.—The origin of vertigo, in many instances, is to be sought in the function of the semicircular canals of the labyrinth. At the present time it may be regarded as established that the function of these structures is to acquaint the individual with the position of his body in space. The sensory tract involved is the vestibular nerve, which innervates the semicircular canals; the other nerves of spinal sense are not involved in this function. The perception, the maintenance, and sense of equilibrium are simply special instances in which this function is employed, and the author does not believe we are justified in regarding the semicircular canals as the mechanism of a special "sense of equilibrium" or of a "static sense." It would seem more correct to designate them as an apparatus for the perception of space. It is equally erroneous to speak of the cerebellum as the organ of equilibrium, simply because it is the first central station for the impulses coming from the semicircular canals. Equilibrium is but one of a number of functions of the cerebellum. The cerebellum serves rather for general orientation in space and for the adaptation of motor innervation to the position of the body; as the first central station, it receives and conducts to higher levels the impulses from the vestibular nerve, and from the direct cerebellar and Gower's tracts. The peculiar and wonderful arrangement of the mechanism for the perception of space need not be discussed in detail; it is enough simply to point out that the three semicircular canals are arranged in the three planes of space and surely are concerned with orientation, since every movement of the body (*i. e.*, of the labyrinth) is analyzed into its three components, each of which exerts an exciting influence upon the nervous elements of one of the semicircular canals. The exciting influence is doubtless due chiefly to the displacement of the endolymph upon the walls of the labyrinth which occurs with every move-

¹ As we shall subsequently learn (p. 1093 et seq.), this may also be the cause of the vertigo.

ment as a result of its inertia. But since we are conscious of our position even during rest, it must be assumed that static pressure effects may also act as the exciting influence which serves as a basis for the perception of space. The nervous impulses arising in this manner are first conducted to the cerebellum by that portion of the auditory nerve called the vestibular nerve. The apparent double function of the auditory nerve seems to justify Ewald's suggestion that it be named the nervous octavus; we should not elevate the vestibular nerve to the rank of a special cranial nerve, for the reason that the current terminology of these nerves is too firmly fixed in our literature. The nervous impulses received by the cerebellum are possibly metamorphosed and then conducted to the cerebrum.

From these physiologic facts it will be understood that a sensation of vertigo always arises when there is a contradiction between the nervous impulses from the semicircular canals and the position of the body (*i. e.*, the labyrinth) or the indication of the other sense organs. This contradiction causes the symptoms of vertigo—uncertainty of judgment, together with the resulting consequences for the motor innervation of the body, particularly for the maintenance of equilibrium, concomitant discomforts, and the characteristic secondary reflexes. In this manner the majority of the clinical symptoms of vertigo are easily explainable.

Vertigo occurs particularly in *affections of the labyrinth* which paralyze or irritate the end-organs in the semicircular canals, and thus lead to a pathologic distribution of the exciting influence and to a consequent faulty perception in reference to the position of the body. The classic example is Ménière's disease, in which the violent pathologic excitation of the semicircular canals produces such marked vertigo that the patient cannot maintain the erect position. In some of these cases the sensory perception of space may be suddenly and completely abolished, and this may result in an interruption of some of the association-fibers, so that unconsciousness is produced. The vertigo which is observed with innocent middle-ear affections is also to be referred to an associated involvement of the labyrinth, either in the form of circulatory disturbances or of variations in the intralabyrinthine pressure. All these cases are characterized as otogenic on account of the simultaneous disturbances of the acoustic function of the auditory nerve, disturbances which take the form of either impaired hearing or the presence of subjective auditory sounds. In these cases conditions either of excitation or paralysis within the semicircular canals may produce the phenomena of vertigo if all the semicircular canals be not equally affected.

The symptoms of vertigo so characteristic of *cerebellar disease* are evidently due to the fact that the stimuli for the sensory perception of space are correctly originated in the labyrinth, but not properly conducted, becoming blocked in the cerebellum. The so-called cerebellar ataxia, so frequently observed associated with vertigo in cerebellar disease, is made up of two components. One of these has nothing whatever to do with the sensory perception of space, but is associated with that disturbance of muscle tone which Luciani has demonstrated in cerebellar lesions. The other component is to be regarded as the motor effect of the vertigo, *i. e.*, the result of the defective correction of movements on account of faulty perceptions of space. (See p. 965.) Since the sensory perceptions of space are prepared in the cerebellum, but do not become conscious sensations and concepts until they reach the cerebrum, it will readily be understood that affections of the cerebrum, as well as those of the cerebellum, may lead to vertigo. The frequent and marked clinical similarity between tumors of the frontal lobe and those of the cerebellum indicates that the frontal lobe contains centers which receive the sensory perceptions of space by means of fibers radiating from the cerebellum and passing through the superior cerebellar peduncles and red nucleus.

The vertigo which occurs as a functional symptom of *circulatory disturbances, cardiac diseases, arteriosclerosis, anemia*, etc., is possibly due to abnormal excitability or abnormal excitation of the semicircular canals or of their coördinated centers. The same applies to *neurasthenic vertigo*.

The vertigo associated with *paralysis of the ocular muscles* is evidently due to a false projection of the retinal images, as a result of which disturbances of space-orientation might naturally give rise to vertigo. These disturbances of space-orientation are due not only to the occurrence of double images, but also to the fact that these retinal images become abnormally displaced during ocular movement, *i. e.*, they do not conform with the motor impulses, so that the objects apparently seem to move. In unilateral ocular paralysis the vertigo may be controlled to a variable degree by having the patient concentrate his attention upon the image produced in the sound eye, and disregard the faulty projection of the image in the paralyzed organ. Even in bilateral paralysis of the ocular muscles the vertigo may

be eliminated if the patient can learn to disregard the visual sense in the formation of his conceptions of space. In all cases the vertigo produced by paralysis of the ocular muscles may be made to disappear by closing either one or both eyes.

A special variety of vertigo, partly also of ocular origin, is that which is experienced upon *rapid rotation of the body* or upon the sudden arrest of a passive movement involving the body, such as the stopping of a train. In the first instance the phenomenon is probably dependent upon the fact that a physiologic excitation is produced in the semicircular canals by the motion imparted to the body, which results in reflex stimuli to the ocular muscles, so that the eyes unconsciously follow external objects in spite of the movement of the body. [Physiologic nystagmus.—ED.] When the particular rotation is very rapid, the excitation of the semicircular canals becomes so strong (all the more as the stimulus increases in the same direction) that the reflex stimulation of the ocular muscles is excessive; since these ocular movements are unconsciously executed, the objects themselves apparently move and vertigo is consequently produced. The inability to fix the eyes permanently upon any object, together with the violence and rapid change in the excitation of the individual semicircular canals, may also be a factor in producing the disturbance of space-orientation in this variety of vertigo. The vertigo which is experienced by many individuals upon the sudden stopping of a train is probably due to the fact that the unconscious reflex ocular movements, produced through the agency of the semicircular canals, are continued somewhat longer than the motion of the train, and the apparent motion of external objects results in vertigo as before.

Mountain vertigo, or the vertigo of elevation, is not a pure vertigo, but is partly due to a sensation of fear. The other factor is probably an ocular vertigo dependent upon a strong concept of falling, which, by autosuggestion, innervates the nervous mechanism of space-orientation to an abnormal degree.

Agoraphobia.—Vertigo produced by the fear of space is brought about by an analogous mechanism which is excited by autosuggestion.

Sea-sickness is probably nothing else than a violent vertigo with numerous irradiations (to the vomiting center, etc.), produced by pathologic excitation of the semicircular canals as a result of the rolling and pitching of the ship. Ocular vertigo plays an important rôle in sea-sickness and originates in the labyrinth, just as is the case in the vertigo produced by rapid rotation of the body or upon the sudden stopping of a train. This is borne out by the fact that a large number of the phenomena of sea-sickness disappear when the eyes are closed. Since the symptoms by no means completely disappear, however, it is quite likely that a further cause is to be found in the inability of the mind and the movements of equilibration to follow the rapidly changing and violent excitations of the semicircular canals. The vertigo in sea-sickness is especially severe because the exciting impulses are constantly undergoing violent variation in a way that cannot be anticipated, and the result is, therefore, a real disease.

Galvanic vertigo, produced by the application of a galvanic current to the head, is doubtless dependent upon a direct and unequal excitation of the nerve-terminals of the semicircular canals, which does not correspond with the position of the body.

The existence of the so-called *gastric vertigo* of Trousseau (*vertigo e stomacho laeso*) in affections of the stomach is doubtful. The majority of the cases answering to Trousseau's description have been shown to be other varieties of vertigo (particularly aural vertigo), the origin of which was unknown in the life-time of this distinguished clinician. In many such cases the only symptom suggestive of gastric disease is the vomiting produced by the vertigo.

V. CEREBRAL LOCALIZATION

Without intending to enter into the question of cerebral localization, which belongs more properly to the province of special diagnosis, the author wishes to submit the following diagrams, to be utilized as a sort of guide in the problems of cortical and nuclear diagnosis:

Fig. 424.—Cortical localization: 1, Trunk; 2, shoulder; 3, elbow; 4, wrist-joint; 5, the three last fingers; 6, index-fingers; 7, thumb; 8, "writing center" (assumed by French writers) (see p. 1107); 9, larynx; 10, Broca's speech center (motor); 11, tongue; 12, mouth; 13, lower facial; 14, upper facial; 15, eye muscle; 16, vision; 17, hearing (Wernicke's sensory speech center); 18, taste; 19, conjugate movements of eyes and head; 20, movements of hip-joint; 21, movements of knee-joint; 22, movements of ankle-joint; 23, movements of great toe; 24, movements of little toes (from Debove and Achard).

See p. 1046 in regard to the central innervation of the conjugate movements of the eyes. Wernicke has assumed that the center for these movements is situated in the inferior parietal convolution, because he found but few projection fibers in this region. He supposes (just as in the explanation on p. 1046) that the conjugate deviation of the eyes, which arises in case of lesions in this area, is due to lesion of an association tract, demonstrated by himself to exist between the visual area and the motor area.

Flechsig disputes this. He locates the "visual center" almost exclusively in the median surface of the hemispheres, especially in the region of the calcarine fissure. The visual disturbances so frequently met with clinically in lesions of this region (16) may be explained partly by the fact that such lesions often involve the visual fibers situated more deeply and connecting the central fibers of the optic tract to the visual center. (See Fig. 443, p. 1116.)

Flechsig¹ places the center of hearing in man (i. e., the central terminations of the acoustic fibers) principally in the anterior transverse parietal convolution which is concealed in the Sylvian fossa and in the contiguous part of the first temporal convolution.

According to Flechsig, the center or area for smell in man has allotment both in the frontal and temporal portion of the brain. The former embraces the entire posterior portion of the base of the frontal lobes and the basal portions of the gyrus fornicatus; the latter embraces the uncinate gyrus and a part of the adjoining inner pole of the temporal lobe. Both portions are fundamentally connected with the island of Reil.

Flechsig, who has recently investigated the localization of the sense of taste, does not furnish any definite statements about its seat; 18 in the diagram is, therefore, placed provisionally.

Munk locates the region for somatic sensibility in that part of the central convolutions and the paracentral lobule supplied with motor centers. (See Flechsig, *Gehirn und Seele*, Leipzig, Veit & Co., 1896.) That is to say, these areas contain, in addition to the motor centers, the central apparatus for sensory appreciations in so far as they do not belong to the "higher" senses (sight, hearing, etc.), which possess special centers. The area for corporeal feeling, according to Flechsig, also includes the lobus limbicus, i. e., the gyrus fornicatus, gyrus uncinatus, and the gyrus hippocampus.

The unshaded areas and the shaded area of the parieto-occipital brain, 16, according to Flechsig, wrongly credited with the visual center, contain the Flechsig association centers. He differentiates three, viz., the frontal or anterior, the parieto-occipitotemporal or posterior great association center, and finally the island of Reil. These areas are anatomically characterized by containing no projection fibers, or very few, and, on the contrary, very many association fibers. Lesions of the anterior association center should cause a loss of interest and a change of character; lesions of the posterior association center, a loss of collective representations, positive knowledge, and mental capacity.

VL. THE DISTURBANCES OF SPEECH

INTRODUCTION

The following chapter on the disturbances of speech and the teachings on aphasia is founded chiefly on the epoch-making works of Wernicke and Lichtheim, but it includes other extensive studies, as well as the author's own investigations. In order to facilitate the task of reference the most important literature on the subject is given below in alphabetic order, although no claims are made for its comprehensiveness.

Literature on Aphasia: Bastian, *On Different Kinds of Aphasia*, British Med. Journal, 1897. Broca, *Sur le siège de la faculté du langage articulé*, Paris, 1861. Dejerine, *Etude sur l'aphasie dans les lésions de l'insula de Reil*, Revue med., 1885. Ibid., *Différentes variétés de cécité verbale*, Mém. de la société de biologie, 1892. Ibid., *Contributions à l'étude anatomopathologique et clinique des différentes variétés de cécité verbale*, ibidem, 1892. Dejerine and Ch. Mirailhé, *Sur l'altération de la lecture mentale chez les aphasiques moteurs corticaux*, Comptes rendus des séances de la société de biologie, Paris, 1895. Dejerine and Vialet, *Contribution à l'étude de la localisation de la cécité verbale pure*, communication faite à la société de biologie, 1893. Grashey, *Ueber Aphasie und ihre Beziehungen zur Wahrnehmung*, Arch. f. Psychiatrie, vol. xvi. Kussmaul, *Die Störungen der Sprache*, Leipzig, 1877. Lichtheim, *Ueber Aphasie*, Deutsches Arch. f. klin. Med., 1884, vol. xxxvi. Naunyn, *Ueber die Localisation der Gehirnkrankheiten*, Congr. f. inn. Medicin, 1887. Oppenheim, *Ueber das Verhalten der musikalischen Ausdrucksbewegungen und des musikalischen Verständnisses bei Aphasischen*, Charité Annalen, 1888. Pick, *Beiträge zur Pathologie und pathologischen Anatomie des centralen Nervensystems*, Berlin, 1898. Sachs, *Vorträge über den Bau und die Tätigkeit des Grosshirnes und die Lehre von der Aphasie und Seelenblindheit*, Breslau, 1893. Wernicke, *Lehrbuch der Gehirnkrankheiten*, 1880. Ibid., *Herderkrankungen des Unterscheitelläppchens*, Arch. f. Psychiatrie, vol. xx. Ibid., *Gesammelte Aufsätze zur Pathologie des Nervensystems*, Berlin, 1893. Wernicke and C. Friedländer, *Taubheit in folge doppelseitiger Läsion des Schläfenlappens*, Fortschritte der Medicin, 1883.

I. THE CONCEPTION OF THE MOTOR SPEECH TRACT

Speech arises from the elaboration of motor speech conceptions in the so-called motor speech center situated in the left hemisphere. When the will is exerted, these conceptions are responsible for the coördinated impulses proceeding through the so-called central speech tract to the bilateral cortical centers for the muscles of speech, thus generating the spoken word.

The speech tract (Fig. 432) originates in the motor speech center, the so-called Broca's area (*a*, Fig. 432), runs to the cortical centers for the oral, laryngeal, and respiratory muscles, some of the fibers possibly passing through the corpus callosum, and finally enters the pyramidal tract to reach the nuclei for the muscles of speech. From the cortical centers to the nuclei of these muscles the impulses travel through the same fibers that are utilized for the other functions of the muscles, so that an actual tract does not exist after the impulse leaves the cortical centers. The earlier assumption of a bundle of fibers belonging to the great psychomotor pathway, which ran directly downward from the center of motor speech to the speech nuclei is invalidated by the fact that motor aphasias are caused by lesions of the region about the center for motor speech only. Lesions in the centrum semiovale, in the crura, or in the pons and medulla produce, at the most, the clinical picture of anarthria, but not that of aphasia.

2. THE DISTURBANCES OF SPEECH FROM LESIONS OF THE SPEECH AREA OR OF THE CONDUCTING FIBERS

The innervation for the movements of speech may be interrupted by a lesion situated in any portion of its course. The clinical picture is subject to great variation, according to whether the lesion affects the speech center, the actual speech tract (the heavy line in Fig. 348), or simply the connection of the cortical centers of the muscles of speech with the nuclei of the latter (the light lines in Fig. 348). In the first instance, even though the lesion be circumscribed, the ability to form words will be more or less completely abolished. When the lesion affects the connection between the cortex and the nuclei of the muscles, however, the only result is a mutilation of the syllables and a disturbance of pronunciation; if the lesion be of moderate extent, the disturbance is but slight, since, owing to the commissural fibers,

the speech impulse is conducted downward from both hemispheres. As a result of the bilateral quality of this portion of speech innervation, the disturbance of pronunciation can be extreme only when the lesion is situated low down in the vicinity of the nuclei for the muscles, where the fibers of both hemispheres are simultaneously more or less involved.

The disturbances having as their cause some lesion in the speech center of the cortex or in the actual speech tract of the left hemisphere are called **aphasias**; those due to some lesion between the cortex and the nuclei for the muscles of speech are called **anarthrias**.

Although in typical cases the clinical distinction between these two conditions is quite marked, the differentiation between them is not sharp, since lesions of the speech center and of the actual speech tract may give rise to symptoms resembling anarthria, providing that the lesion is neither large nor destructive (see Anarthria). Such a disturbance, which might be called a "central anarthria," may, nevertheless, be differentiated from a peripheral anarthria, and particularly from that caused by a lesion in the vicinity of the nuclei, by the fact that in the latter the other functions of the muscles of speech (deglutition, mastication) are also involved.

The sharpest differentiation between aphasia and anarthria consequently consists of the fact that the former is purely and exclusively a disturbance of speech, while the latter is always accompanied by a disturbance of the other functions of the muscles of speech.

(a) **Anarthria**

In anarthria there is an affection of individual fibers of the speech tract in the neighborhood of the nuclei. Hence the following peculiarity: The speech im-

Fig. 432.—Diagram of the motor speech tract. For simplicity, of the nerves which subserve the function of speech, only the facial (*VII*) and hypoglossal (*XII*) are shown. For the center for voluntary breathing, as well as that for the larynx, see Fig. 425; and for the motor trigeminus, especially for the part that presides over the movement of the jaws, see "Chewing," Fig. 425. The figure also fails to picture the commissural fibers coursing in the corpus callosum, which unite the two lateral cortical centers.

pulse is correctly formed in the speech area and correctly despatched to the periphery; but, as the result of partial interruption of conduction in the neighborhood of the

nuclei, its ganglion-cells no longer receive the measure of innervation essential to coördinated speech. The result is a disturbance in the coördination of speech, analogous to the ataxia of the extremities in partial paralyses (see p. 964 et seq.), so that a patient with anarthria pronounces the word with approximately correct cadence of syllables and intonation, but with some of the letters of the word lacking or else incorrectly pronounced. Anarthria is, therefore, a disturbance of pronunciation, which is characterized by the fact that the more or less marked paralysis of the muscles of speech also affects the other functions of these muscles.

It is evident that quite an analogous disturbance of speech will arise when not the terminal fibers of the speech tract in the neighborhood of the nuclei, but the nuclei themselves or the peripheral speech nerves (*e. g.*, facial and hypoglossal) are affected. In such cases speech will be mutilated and pronunciation will suffer. These nuclear and altogether peripheral disturbances of speech parallel those of supranuclear anarthria, inasmuch as they are associated with paralyses of other movements.

The clinical picture of anarthria may, under some circumstances, result even from an incomplete involvement of the speech center or of the actual speech tract. This can be explained only by assuming that the separate fibers or cells are to a certain extent individually diseased, or that the disturbance is purely functional without gross anatomic changes, because the fibers of the central speech tract are so compact that larger lesions generally affect them in toto. Anatomic proof of the existence of pure anarthria depending upon such individual disease of separate fibers or cells has not yet been furnished. Anarthric disturbances of pronunciation, which often persist for a long time after recovery from aphasia, or accompany incomplete aphasias, may without doubt be explained by the fact that certain individual fibers or cells of the central speech apparatus, which is at first widely involved, later on recover, while certain others do not. In the same way manifold combinations of anarthria and aphasia, which have been sometimes observed in incomplete aphasia, may perhaps be attributed to an unequal involvement of the central speech apparatus. As has previously been stated, the characteristic of all these cases of "central anarthria" is that the muscles perform all their movements except those necessary for the production of speech.

The simplest method of examining for anarthria is to have the patients pronounce the letters of the alphabet in their order, and then combinations of letters, *i. e.*, simpler and then more complicated words. Theoretically, it is evident that anarthria will occur very frequently in all lesions in the neighborhood of the nuclei of the speech muscles, *i. e.*, in hemorrhagic and softened areas and in tumors of the pons and of the oblongata, but especially in progressive bulbar paralysis.

(b) Aphasia (Agraphia; Alexia)

Mechanism of Interior Language

As contrasted with anarthria, we may define aphasia as embracing those disturbances of speech which arise from more or less complete interference of the func-

Fig. 433.—Primitive speech apparatus of the child for mechanical repetition of words: *a*, Sensory speech center (Wernicke's convolution); *b*, motor speech center (Broca's convolution); *ba*, motor speech tract; *ma*, acoustic tract (concerning those anatomic conceptions, see p. 1110). (For the anatomic relations, see Fig. 435.)

tion of the actual speech tract or of the motor speech center itself. If we could represent the latter as a mere center, the process would be comparatively simple; the arrest of function, both of the center (Fig. 432, *a*) and of the tract (heavy line, Fig. 432), would cause loss of speech or aphasia.

The conditions of aphasia are, however, more complicated, because the speech center is, in a broader sense of the word, not a simple motor center. We may consider the entire apparatus of central speech formation, which has been established psychophysiologically by the researches of Wernicke and Lichtheim, as proceeding centrally from the point *a* of Fig. 432, and this latter point as representing merely the motor terminus of the central speech mechanism, the so-called motor center of speech. Lesions of these portions of the speech apparatus, which have not yet been studied, can also give rise to disturbances properly designated as *aphasias*. To understand these different forms of aphasia, a knowledge of the physiologic mechanism of central speech formation is, therefore, required. A more exhaustive discussion, essentially following Wernicke and Lichtheim, must now be given.

When a child learns to speak, the sound of the word heard is sent by way of the acoustic nerve to the cortex of the left first temporal convolution (sensory speech center, Figs. 433 and 435). The child then attempts to imitate this word. This latter procedure may be explained by assuming that, by means of association, the auditory images beget a conception of movement corresponding to the spoken words. This representation of movement, as Broca proved, is situated in the left inferior frontal convolution (motor or Broca's speech center, Fig. 424, 10). The

Fig. 434.—Apparatus for conscious speech and speech comprehension, with the relationship to the primitive speech center to concepts, especially the sensory division of the latter. For simplicity, merely three divisions of the cortical sensory areas have been represented. The letters *a*, *b*, *x*, *m*, and *n* have the same meaning as in Fig. 433.

child's primitive speech apparatus (Fig. 433) is formed in this way, and he thus repeats mechanically the word spoken. *a* represents the center for auditory images of the word heard, *i. e.*, the *sensory speech center* in the first temporal convolution. The auditory images are received here after they have properly stimulated the corresponding acoustic center, the center of simple hearing or sound perception. The anatomic course of these tone images will be considered later on. (See p. 1110 et seq.) The association tract (*ab*) which, by mechanical babbling of the child, incites the center *b* by way of *mab*, runs, according to Wernicke, along the convolutions of the island of Reil from behind forward. The arrow pointing upward represents the tract of the auditory nerve (in so far as it concerns excitation of word images, see p. 1110); the arrow pointing downward from *b* represents the motor speech tract shown in detail in Fig. 432.

The child's advance to the stage of voluntary speech is attained through the association of centers (*a*) and (*b*) with concepts. The concept of an object is the aggregate of its partial representations. The concepts are acquired by experience, in that these partial representations are stored and associated as memories in the different sensory areas of the cortex.

The concept of an object can, therefore, never be localized at a single point in the cerebral cortex, *e. g.*, the concept "bell" requires association tracts to quite different parts of the brain to the acoustic, optic, and tactile centers. This is repre-

sented in the more complicated diagram (Fig. 434). The partial concepts $c + c' + c''$ first produce the concept bell.¹

To simplify the speech scheme, we reduce the concept $c + c' + c''$ to a single point (C), using the diagram that Wernicke first made for voluntary conscious speech (Fig. 436). The significance of the double arrows will be explained in what follows. The diagram shows that voluntary speech follows the path Cbn (Fig. 436),

Fig. 435. The central areas of speech, according to von Monakow. Lateral view of the left hemisphere. Speech area shaded, the relative fields somewhat lighter; FS, Fissure of Sylvius; rha, rhp, ramus horizontalis anterior and posterior, of the fissure of Sylvius; Gca, Gcp, anterior and posterior central convolutions; F₁, F₂, F₃, first, second, and third frontal convolutions, Fc, central fissure; JP, interparietal sulcus; O₁, O₂, O₃, first, second, and third occipital convolutions; T₁, T₂, T₃, first, second, and third temporal convolutions; P, superior parietal lobule; P₁, inferior parietal lobule; supramarg., gyrus supramarginalis; angul., gyrus angularis.

repetition (by avoiding its point C) follows the path $mabn$ (to a certain extent just as do the reflexes), and the comprehension of spoken language follows the path maC .

The Aphasic Disturbances Without Reference to Written Language (Reading and Writing)

With the aid of this diagram we can readily explain many types of aphasia by supposing interruption of conduction at different places. We differentiate between motor and sensory aphasia according to whether the interruption affects the sensory centripetal (maC), or the motor centrifugal conducting portion (Cbn). Aphasia arising from interruption of conduction in the line ab is spoken of as "conduction" or, perhaps better, "association aphasia." Disturbances between a or b , on the one hand, and C , on the other, are called *transcortical*, those in a and b *cortical*, and those peripheral to a and b *subcortical*. These names have not been fittingly

¹ To avoid misunderstanding, the author should add that the concept which a child has of a bell and associates with the word "bell" is, of course, not the complete concept of a "bell" which an adult possesses. A complete concept will only be developed gradually, in the course of mental development, by adding one partial concept to another. Thus, in small children, the concept of a "bell" may be exclusively the partial representation of the tone of a "bell" and perhaps of some of its metallic luster; then, in the course of development, are superadded the concepts of the form of the "bell," of the sensation of cold by touching it, of its use, and of many other features to complete the concept.

chosen, since the entire area of innervation (*abc*) is situated in the cerebral cortex,¹ and should, consequently, be designated as cortical. If the terms had not become so fixed, the author would suggest replacing them by the expressions transcortical, cortical, and subcortical, the word "cortical" naturally referring to the speech center.

To explain these different symptom-complexes, we must now call attention to the fact that, for correct speaking, the tract *Cab* must be intact, as well as the tract *Cbn*, although this does not directly appear in the diagram. If the tract *Cab* be interrupted at any point, or the center *a* be destroyed, one might believe that only the sensory function of speech, *i. e.*, comprehension of speech and not its externalization, would be affected. Experience teaches us, however, that in this lesion speech is, as a matter of fact, possible by way of the tract *Cbn*, but that a symptom called *paraphasia*, *i. e.*, confusion of words (see below; the symptoms of central and transcortical sensory aphasia), is regularly observed, because the control of the motor innervation by way of the path *Cab* is essential for correct speaking. Since this *paraphasia* may also be caused by lesions between *C* and *a* (see below, transcortical sensory aphasia), it must be assumed that not only centripetal, but also centrifugal, conduction, requisite for the control mentioned above, is situated in the association fibers *aC*. Words are sounded inwardly. The double arrows in Fig. 436, between *a* and *C*, represent this idea; but it must be assumed that the innervation from *C* to *a* is not sufficient to speak by way of *Cabn*, as otherwise no loss of speech would occur with a lesion between *b* and *C*, and experience proves that this is not the case. The

Fig. 436.—Simplification of the diagram of conscious speech (Fig. 434) by restriction of the conception to point *C* and the omission of the acoustic center *x*. The letters have the same meaning as in both preceding diagrams. The figures correspond to the list of aphasias in the text.

double arrow between *a* and *C* also indicates that, in addition to *paraphasia*, a disturbed naming capacity is peculiar to central and transcortical aphasia. This phenomenon, which is essentially closely related to *paraphasia*, consists in a difficulty to find the proper name for objects and ideas, because of a disturbed association between the concept and the auditory image. *Paraphasia* is developed from this whenever the patient, in his desire to talk, does not experience its inhibitory effect.

The following main types of aphasic disturbances should now be easily understood. The numbers represent the point of interruption as indicated in the diagram (Fig. 436):

1. *Central (Cortical) Sensory Aphasia*.—Comprehension of speech and repetition of speech are prevented. *Paraphasia* is present. Naming is disturbed. Objects are usually named wrongly.

2. *Subcentral (Subcortical) Sensory Aphasia* (Pure "Word-deafness").—The same functions are interfered with as in 1, except that there is no *paraphasia*, and no difficulty in naming. (See below, differences in regard to written speech.)

3. *Transcortical (Transcortical) Sensory Aphasia*.—Comprehension of speech is lost; repetition of speech (in contrast to 1) is retained. *Paraphasia* is present. Difficulty in naming is also characteristic. Objects are named wrongly.

¹ This is demonstrated by the fact that the lesions producing aphasia are always situated in the cortex or in its immediate vicinity. At most the tract *am* (the heavy line in Fig. 432) describes but a slight curve in the white matter in the vicinity of the cortex.

4. *Central (Cortical) Motor Aphasia* (Broca's Aphasia).—Spontaneous speech and capacity to repeat are lost. Comprehension of speech is preserved.

5. *Subcentral (Subcortical) Motor Aphasia* (Lesion of the Speech Tract; Pure Word Dumbness).—Clinical picture as in 4. Differentiation between 4 and 5 with regard to syllable counting and written speech is discussed below.

6. *Transcentral (Transcortical) Motor Aphasia*.—Spontaneous speech is lost. Repetition and comprehension of speech are preserved.

7. *Conduction or Association Aphasia*.—Comprehension of speech is preserved. Spontaneous speech is paraphasic. Repetition by way of *aCb* is possible, but also paraphasic. Naming is difficult. Positive cases of this kind of aphasia have not been observed. (See p. 1113.)

Difficulty in "naming" (see explanation, p. 1105) is common to the first and third form of sensory aphasia. With it, and with the necessity of using a limited stock of words, is associated agrammatism, so frequently observed during the stage of recovery from sensory aphasia. It consists in a sort of telegraphic style, i. e., of sentences without construction.

A type of syllable stuttering that cannot be distinguished from that of general paresis is very prominent during the subsidence of Broca's (central motor) aphasia, or in incomplete varieties of the latter.

A differentiation between 4 and 5 can be determined by examining the written speech. In central motor aphasia (4) writing is impossible; in subcentral (5) it is preserved. Further discussion of this point will be taken up later. Lichtheim has demonstrated that a patient with subcentral motor aphasia (5) can show by signs how many syllables there are in the name of an object held in front of him; whereas, with central motor aphasia (4), destruction of the center (*b*), this is impossible, although one might think that syllable counting could take place at the center for auditory images (*a*).

The varied disturbances of writing and reading which occur in aphasia show that the centers *a* and *b* have an almost reciprocal relation, expressed in Fig. 436 by the double arrows, and that the sensory and the motor concepts together produce the unit of so-called word conception (Wernicke) (see p. 1107). In this collective word conception, and not merely in the individual concepts (*a* and *b*), are to be found not only the letters, as we shall see, but also to a certain extent the number of the syllables, presupposing an internal speech. Therefore, in case there is an injury in *a* and *b* or between the two, the patient can no longer determine the number of syllables in a word corresponding to some conceived object. Thus far the author believes this phenomenon has been attributed only to lesions in *b*; that is, to central motor aphasia (4). However, if this explanation be correct, it must also occur in central sensory and in association aphasia.

The reasons why all aphasias have not been given among the forms described above will appear later on p. 1118.

Disturbances of Written Language Associated with Aphasia

In determining the characteristics of an aphasia, we must inquire into written speech, i. e., the ability to write and to read, for this is closely connected with articulate speech. This gives the clinical pictures of the different forms of aphasia a much more sharply defined character, since the functions of written speech appear differently in these disturbances, according to the location of the lesion.

To explain the psychic mechanism of reading and writing, one cannot do better than to start again with the development of this function in children.

The child learns to read and write by having the optic pictures of the letters imprinted upon a center (*a*, Fig. 437) (the position will be indicated later); and by learning at the same time to associate with them the corresponding auditory images. This association results from the formation of a tract (*a a*), in which *a*, as in Fig. 436, represents the sensory (acoustic) speech center. By means of such an association, printed or written letters acquire a definite significance to the child. In learning to write, a child forms an association between the optic center (*a*) and a motor center (*β*), and making use of *β*, learns to copy the letters mechanically. There first occurs an impression of sensory memory pictures (here by way of the optic), an almost simultaneous association of these with acoustic memory pictures, and then a production of movement concepts for writing the separate letters. Therefore, we assume that copying letters by a child occurs by way of the tract (*uaβv*).

Thus far we have included in the child's learning written speech only the mechanical copying of letters. Very soon, however, he learns to write letters when merely their auditory images have impressed him, either from dictation or of his own accord.

representing on paper the letters resounding spontaneously in his mind. To explain the process of writing letters voluntarily or from dictation, we must introduce into our diagram still another centrifugal tract, which unites the diagram of writing with that of speaking. We have already in the tract aa (Fig. 437) a centripetal connection of the writing mechanism with a sensory speech center; the line ba may represent the centrifugal connection between the motor speech center (b) and the psychic writing mechanism. The mechanism of writing described above and personal observation show us that this connection occurs from b to a and not from b to β , since we always arouse the optic letter image first in writing and then produce it by means of our motions. Writing letters voluntarily or from dictation takes place, then, in this way: a is stimulated by the auditory images of the letter emerging from the mind, and excites in b the concept of movements of the spoken letter, then the optical picture in a , and from there finally the movement concept of the written letter in β .

The point β has oftentimes been supposed to exist as an actual writing center (Charcot, Exner, Pitres, Ziehen); and Exner located in it the second frontal convolu-

Fig. 437.—Diagram for the mechanism of written speech: a , Center for the optic concepts of written or printed letters apparently corresponding to the bilateral cortical optic center (p. 1115); μa , optic tract (see p. 1115); a , sensory speech center; b , motor speech center; C , concept; β , β' , β'' , motor centers for writing movements (β for writing with the right hand; β' and β'' for writing with other parts of the body); βv , $\beta' v'$, $\beta'' v''$, motor tracts for writing movements. The numbers 8 to 14 represent the locations of lesions in the so-called isolated alexias and agraphias. (See p. 1113.) For simplicity only, the heavy lines should be noticed at first in reading the text.

tion on the left side, near the middle of the anterior central convolution. (See Fig. 1095, 8.) Simple reflection shows that such actual writing center does not exist. The movement of writing is, as a matter of fact, like any other movement, in case the form of the letter is known; one can write it with any part of the body, for example, the nose or the foot. We can go even so far as to place the supposed writing center in the brain of the horse when we describe the form of a letter by riding. As a matter of fact, we write by copying approximately the optical memory pictures of letters, using any sort of movements. Ordinarily, β represents the cortical center of the right hand; it could, however, just as well represent another motor center. The dotted tracts $a\beta'v'$, $a\beta''v''$, etc. (Fig. 437), are intended to express this multiplicity. Including only the essentials of Figs. 436 and 437, a diagram of the central speech mechanism, including reading and writing, may be represented as in Fig. 438.

The following explanation should be added to explain reading and writing entire words. Experience teaches that written speech is always disordered in aphasias if there be an injury anywhere upon the line ab , whether it be at a or at b , or between the two; for, as mentioned upon p. 1106, a and b seem like a unit, which Wernicke has designated as the "substratum of the word conception." Now, it

is ordinarily assumed that the word conception is produced from separate letters, that the tract *aab* is traveled by each letter, and that in writing entire words the conception will be dissected, so that an innervation impulse proceeds from *b* to *a* for each letter. It might be said against the theory of reading by spelling, and in favor of the theory that optic memory pictures of entire written words are stored up in the brain, that in the speed-reading of experts, not merely words, but sentences, and even whole pages, are glanced over in an interval apparently too short for the time required for the individual conduction of words. This objection is really not valid, however, because the curtailment of the procedure, through practice, depends upon the evocation of acoustic word-memory images, through the perception of characteristic letters or combinations of letters, and not upon the apperception of optic images of words, sentences, or whole pages as such. In this manner the sense of words is conjectured from the letters, sentences from characteristic word combinations, and pages from peculiar sentences. The ability to conjecture, *i. e.*, to supply the deficiencies in perception, plays a very important part in shortening the time of apperception of sensory impressions. In the same way, only a cursory glance at the unusual styles of print on the modern posters at every corner is necessary, although a direct recognition of these very unusual optic word images, seen perhaps for the first time, is manifestly inconceivable. The ability to decipher illegible handwriting might be adduced as further proof. In many of these instances it is hardly a question of real letters at all, and one might

Fig. 438.—Diagram of the entire central speech apparatus, including reading and writing. The letters and the figures have the same meaning as in the two preceding illustrations.

think that entire word images are read. This is impossible, however, because the forms of these distorted, illegible word images vary so in each instance that they cannot be stored up in the brain as memory pictures. The mechanism consists rather in the recognition of individual letters, the characteristic grouping of which permits the conjecture of the rest, *i. e.*, the whole word. From the words, even if there be many undecipherable ones, we guess the sense of the sentence, as every one who has had experience can confirm.

Of course, this applies only to languages (European) which possess an alphabet. The nations whose words are not constructed from letters, but consist of particular and inseparable diagrams, *e. g.*, hieroglyphics of the ancient Egyptians and the word-writing of the east Asiatics (Chinese and Japanese), are evidently subject to different conditions. In this instance we must assume that only optic word images are stored up as memory pictures in the optic area, and, therefore, a lesion of the word idea, *a + b*, would not lead to the same disturbances of writing and reading as among Europeans, since in writing, the optic word images, avoiding the points *a* and *b*, are probably directly associated with the word idea. A similar condition occurs among peoples who make use of an alphabet with separate symbols for the numbers, *i. e.*, reading and writing of the latter may be intact in central aphasia, in which writing and reading (lesion at *a + b*) is severely disturbed. (See p. 1119.) The theory that the numeric symbols do not have the same position as the other characters, in that they are directly associated with the numeric concepts and avoid the points *a* and *b*, best explains this.

It follows that a language constructed from word symbols is much less complete than one founded upon an alphabet, since the acquisition and use of the former are a severe tax on the memory. It is not difficult to foresee how much greater would be the number of those who would forget the characters soon after learning them, or to whom the art of reading and writing would remain quite foreign, if we possessed a symbol language; this was surely the condition until lately among the east Asiatic peoples. The difficulties of symbol writing are somewhat analogous to the clumsy and comparatively useless method of printing by woodcuts before the invention of individual type. One may say that, in regard to science at least, the progress of nations is associated with letter language, just as the introduction of separate type rendered possible the advent of the renaissance, and in particular the progress of science. In spite of their centuries of civilization, the east Asiatic nations until recently have been absolutely dependent on Europe as the source of their scientific knowledge; a fact that is surely due to want of a letter language (a strong movement for its introduction is now under way in Japan); for it has robbed them for centuries of the most convenient and democratic means of acquiring and propagating scientific knowledge.

After what has been said, it is plain that written speech (including both the reading and writing of words) will always be affected if the word concept (*a* and *b*) be injured in any way, that is, if the lesion be situated at *a*, at *b*, or between *a* and *b*. This applies, on the one hand, just as much to reading aloud as to the comprehension of written speech; and, on the other hand, just as much to spontaneous writing as to writing from dictation. An interference in mechanical copying, however, in which one letter is pictured after the other, always depends upon a lesion in the territory of the writing arc ($\mu\alpha\beta\nu$). Mechanical copying is something quite apart from the speech function. Like drawing, it is a sort of mechanical skill which depends upon the association of optic memory pictures and apperception, on the one hand, and upon the coördinated innervation of the hand muscles on the other. It is worthy of note that, because a lesion between *a* and *b* destroys the word concept, it makes writing quite impossible, or occasions a very marked defect in it, but never leads to paraphasia. The latter is analogous to paraphasia, and produces only a confusion of words in writing. Paraphasia occurs only in transcortical sensory aphasia (see below, 3), and according to the law that the complicated functions suffer the most, it may be very marked in cases in which paraphasia is insignificant.

The effects of the different kinds of aphasias on written speech (see p. 1105) are as follows¹:

1. *Central (Cortical) Sensory Aphasia*.—Lost: voluntary writing to dictation, comprehension of writing, reading aloud. Retained: mechanical copying.

2. *Subcentral (Subcortical) Sensory Aphasia* (Pure Word-deafness of Lichtheim).—Written speech is quite unaffected. This is very rare and may be confused with a high-grade diminution of hearing, especially as a certain diminution of the acuity of hearing may be associated with it. (See p. 1111.)

3. *Transcortical (Transcortical) Sensory Aphasia*.—Lost: comprehension of writing. Retained: reading aloud without comprehension, and writing in all its forms. Paraphasia (written paraphasia, see p. 1105, 3) is, however, present in spontaneous writing, *i. e.*, the words are confused, just as in speaking.

4. *Central (Cortical) Motor Aphasia*.—Lost: all forms of writing and reading, with the single exception of mechanical copying. See p. 1118, in regard to the persistence of apparently isolated agraphia in recovering cases. Von Monakow observed the capacity for writing preserved in a case in which a circumscribed lesion was found in Broca's center.

5. *Subcentral (Subcortical) Motor Aphasia* (Pure Word Dumbness).—Lost: reading aloud. Retained: writing in all its forms, and the comprehension of writing.

6. *Transcortical (Transcortical) Motor Aphasia*.—Lost: spontaneous writing. Retained: writing to dictation, copying, reading aloud, and the comprehension of writing.

7. *Conduction or Association Aphasia*.—Lost: all kinds of reading and of writing, with the exception of mechanical copying. Definite clinical cases of this sort are unknown. (See p. 1111.)

In these disturbances dependent upon aphasias, the writing and reading of individual letters are generally quite the same as the writing and reading of entire words.

¹ The numbers correspond to those in Fig. 438. (See p. 1108.)

The occurrence of mirror-writing in aphasia requires some mention in this connection. If a patient suffering from aphasia with paralysis of the right hand can write at all, i. e., in subcortical motor, subcortical sensory, or transcortical motor aphasia (retention of word concepts), he will frequently write *en miroir*, instead of the usual script, when requested to write with the left hand. The phenomenon has been attributed to the aphasia, but, as normal individuals also possess a similar tendency to execute mirror-writing whenever they attempt to write with the left hand, such an explanation is manifestly incorrect. This tendency may only be overcome by a distinct effort of the will, and it is due to the fact that, in the use of the right hand, the left, through the associated acting of symmetric muscles, is unconsciously exercised in mirror fashion. Hence it is obvious that for hemiplegics, in whom the left hemisphere has been excluded by the paralysis of the right hand, it would become more difficult to master the inclination to mirror-writing.

The Real Anatomic Nature and Position of the Points and Lines of the Speech Diagrams, and the Anatomic Localization of the Individual Forms of Aphasia

Wernicke and Lichtheim have shown that an aphasic lesion, which has been localized theoretically in the psychophysic diagram (Fig. 438, p. 1108), may also be localized anatomically if we are familiar with the positions of the tracts and centers of the speech area.

In the first place, it is necessary to refer to the fact, demonstrated on p. 1101, Fig. 432, in the discussion of the relationship of Broca's, or the motor speech center

Fig. 439.—c, Central sulcus; o, parieto-occipital sulcus; i, intraparietal sulcus; k, anterior occipital sulcus; g, inferior occipital sulcus; St.L., frontal lobe with its three convolutions (I, II, III); g.c.a., anterior central convolution; g.c.p., posterior central convolution; O.S.L., superior parietal lobule; U.S.L., inferior parietal lobule; Q.L., occipital lobe; gm., gyrus marginalis; g.a., gyrus angularis; x x, connecting gyrus between parietal and occipital lobes; a, b, and m, correspond to the letters in diagram 438. The dotted lines radiating from the points a and b represent transcortical association of ideas (Fig. 434, p. 1103.)

to the motor speech pathway, and first established by Marc Dax, that central speech is located normally in the left hemisphere only. Left-handed persons constitute the chief exception to this rule, since it has been demonstrated by pathologic findings that their central speech is a function of the right hemisphere. Normal left-sided speech is associated with the normal activity of the left hemisphere and of the right hand, although the reason for the wide-spread preponderance of the latter is still unknown. It is quite evident, however, that the unilateral localization of the delicate motor functions of the hand, as well as the more complicated speech function, indicates an economy of power for the brain. Schreiber has reported rare cases (see p. 1120) of aphasia in right-handed individuals in whom the faculty of speech was located in the right hemisphere. In other exceptional cases, cited by Wernicke, the aphasia disappeared, although a complete destruction of the left zone of language was subsequently demonstrated. In these cases a vicarious exercise of the speech function on the part of the right hemisphere must be assumed. As a matter of fact, a complete recovery from motor aphasia occurs only in children capable of education, whereas in sensory aphasia, the deficiencies are frequently restored, as Wernicke has shown, through the acquisition of word-memory pictures by the right hemisphere. This must not be confused with the disappearance of aphasias which have been caused by pressure instead of destructive lesions.

In regard to the centers and tracts assumed in the theoretic diagram, and without heed to the question of localization of the speech function on the right or left side, we have seen that Broca's or the motor speech center (*Ca* in Fig. 438, p. 1108) is situated in the foot of the inferior (third, according to the usual terminology, but first developmentally) frontal convolution, *i. e.*, the part next the anterior central convolution. The sensory, or Wernicke's center of speech (*b*, Fig. 438), is located in the posterior part of the superior and a contiguous part of the middle temporal convolutions. The path *bn* (motor speech tract, Fig. 438) represents an association tract, which passes from Broca's area to the psychomotor center in the faciolingual area, and penetrates only slightly the subjacent white matter. The association path, connecting the motor and sensory speech centers (*ab*, Fig. 438), passes through the region of the insula. These relations are represented in the anatomic diagram first, and the designations correspond to those of Fig. 439. The association tracts, *Ca* and *Cb* of Fig. 438, *i. e.*, connections between concepts and motor and sensory centers, have been indicated, as far as possible, in the same diagram. Fig. 434, p. 1103, shows these paths more accurately in their anatomic relation than the purely theoretic diagram of p. 1108. There are very many paths between the speech centers and all parts of the brain, where ideas and memory pictures are deposited, and, as it would be impossible to indicate them as lines in the anatomic figure, they appear as radiations from the points *a* and *b*. We must conceive them as spreading out over the

Fig. 440.—Probably an incorrect conception of the relations between the acoustic word-picture center and acoustic perception.

whole thinking part of the cortex, although, for the sake of simplicity, they are indicated for a short distance only beyond the points *a* and *b*.

This method of schematic representation shows that transcortical or transcentral tracts cannot be completely interrupted by an extensive lesion without implicating either of the corresponding centers, *a* and *b*. The insula and inferior temporal lobe also contain a large number of transcortical or transcentral tracts, which terminate in both motor and sensory speech centers, and a lesion of these causes the so-called unclassified aphasias.¹ Furthermore, as the path *ab* is not the only one passing through the insula, we have no reason to expect that a lesion of this structure could cause the purely theoretic and clinically uncertain picture of conduction aphasia.

The author believes that the acoustic tract (*ma*, Fig. 438) represents a group of fibers, a lesion of which causes the symptom-complex of subcentral sensory aphasia or pure word-deafness. Pure word-deafness is due to an interruption of the centripetal acoustic stimuli which arouse the acoustic word representation, and it consists in the loss of comprehension of spoken language, with integrity of the other speech functions and without pronounced deafness for other sounds. In the former editions of this work the author has assumed the tract *ma* to be a pathway connecting the center of the acoustic nerve with a special center for the acoustic word-memory images, as shown in Fig. 438.

¹ Naunyn, Cong. f. Med., 1887.

A division of the central organ of the acoustic nerve into a center for sound perception and a center for word-memory images is not in accord with the much simpler theory that ideas caused by association and perceptions resulting from sensory impressions, are localized at the same time in the cortex, and are differentiated by the kind of excitation only. The latter theory has never been disproved by pathologic study. The radiation of the acoustic fibers toward the cortex also renders such a division purely hypothetic and superfluous for the explanation of subcentral sensory aphasia. As a result of many studies, it may be regarded as settled that each acoustic nerve is connected with both hemispheres, thus following in its central course the type of bilateral innervation of most cranial nerves, and possessing a semidecussation like the optic, for example.

The optic tract terminates primarily in the pulvinar, the anterior corpus quadrigeminus, and external geniculate body; in a similar manner the acoustic fibers terminate primarily in the posterior corpus quadrigeminus and the internal geniculate body of the same side; the then impulses pass onward, through the brachium conjunctivum and stalk of the geniculate, to the first and second convolution of the temporal lobe. The central part of the acoustic fibers above the decussation thus contains fibers from both acoustic nerves, and we may complete the analogy to the optic tract, and call it the acoustic tract.

A unilateral lesion of the temporal lobe or of the fibers of the acoustic tract (lesion *x* and *y*, Fig. 441) does not cause unilateral deafness, as may be seen from the

Fig. 441.—Diagram of central acoustic innervation. For the sake of clearness the right acoustic tract is represented only so far as the primary acoustic center. It must be imagined as terminating on the right side of the diagram in the cortex and communicating with the callosal fibers.

figure. At most, it can only cause a moderate diminution of hearing in both ears, hard to demonstrate, because both acoustic organs are still in communication with the hemisphere opposite the lesion. On the other hand, the symptom-complex of subcentral aphasia does not follow any arbitrary lesion of the left acoustic tract, *e. g.*, near the posterior corpus quadrigeminus, (*x*, Fig. 441), as clinical observations will show. The lesion must be located either in the cortex of the left temporal lobe (Veraguth's case) or in (lesion *y*, Fig. 441) its immediate vicinity (Liepmann's case). The theory which best explains this is that the sensory speech center receives acoustic stimuli circuitously from the right temporal lobe in addition to those passing along the left acoustic tract, and that these two sets of stimuli can be simultaneously interrupted only at a joint near the cortex of the left temporal lobe. The connection of the sensory speech center with the right temporal lobe occurs through the corpus callosum, and is indicated by the dotted arc in the accompanying figure. *y* represents the meeting point of the stimuli, coming from the right temporal lobe, with those of the left acoustic tract, and a lesion at this point only will cause subcentral word-deafness. There need be no more than a slight reduction of hearing in such a lesion, as the diagram will show, because each acoustic nerve is still in communication with the apperceptive center of the right side. The path *ma* (Fig. 438) represents anatomically the sum of the fibers of the left acoustic tract plus the callosal acoustic fibers. The point in the anatomic diagram (Fig. 441) where the fibers of the left acoustic tract and of the corpus callosum meet, a lesion of which (*y*) causes subcen-

tral aphasia, corresponds to the letter *m* of the theoretic diagram (Fig. 438), although the latter cannot be indicated in the surface view of the brain. With the exception of Liepmann's case, in which a subcortical lesion of the white matter seemed to be the anatomic cause of a pure word-deafness, the lesions have thus far been found either in both temporal lobes (Dejerine) or else in the cortex of the sensory speech center, and this agrees exactly with the author's conception. In Dejerine's case the lesion of the left side evidently destroyed the fibers of the acoustic tract, and that of the right destroyed the callosal connection between the two temporal lobes. The lesion in Veraguth's case, on the other hand, although cortical, was of such a nature that it did not totally obliterate the sensory speech center, but interrupted the conduction of impulses to it instead (just as at *y*, Fig. 439). There is a well-known analogous condition in motor aphasia, *i. e.*, when the symptom-complex of subcentral motor aphasia is due to a small circumscribed lesion of Broca's area. Here, again, the motor speech center is obviously not affected, but simply the association tract leading to the faciolingual area in the anterior central convolution (*bn*, Fig. 439, p. 1110). The author believes that observations of this sort warrant the substitution of the term subcentral for subcortical.

The isolated disturbances of written speech do not really belong to true aphasia, and the nature and position of the tracts *aa* and *ba* will be discussed in the following section.

*The So-called Isolated Disturbances of Written Speech Independent of Aphasias (Isolated or Literal Alexias or Agraphias)*¹

Besides disturbances in writing and reading dependent upon aphasias, there may also occur disturbances of written speech which are independent of the aphasias. This will be the case when a lesion occurs in the lower part of the diagram (Fig. 438), *i. e.*, in the writing arc and in its connections with the central speech apparatus (in the radius of lesions, 8-14).

These disturbances, as contrasted with those depending upon aphasias, may be termed *isolated alexias* and *agraphias*. According to the diagram, seven such disturbances are theoretically possible, for which a similar terminology may be employed as for the aphasias (Fig. 438).²

8. *Subcentral Alexia* (Injury between μ and α ; "Pure Literal Blindness").—Reading of letters and words impossible; writing of letters and words, with the exception of copying, possible.

9. *Subcentral Agraphia* (Injury between β and ν).—Reading of letters and words retained, but words can neither be written nor copied. (See below for the significance of this form.)

10. *Central (Cortical) Alexia* (Injury at α).—Letters and words can neither be written nor read, and even copying is impossible.

11. *Central (Cortical) Agraphia* (Injury at β).—Letters and words can be read but not written nor copied (as in 9). (See below for the significance of this form.)

12. *Conduction or Association Agraphia* (Injury between α and β).—Letters and words can be read but not written nor copied (again as in 9 and 11). (See below.)

13. *Transcentral (Transcortical) Alexia* (Injury between α and α).—Reading of letters and words impossible. Writing of letters and words, including copying, possible.

14. *Transcentral (Transcortical) Agraphia* (Injury between b and α).—Reading of letters and words possible. Writing of letters and words, except mechanical copying, impossible.

In the narrow sense of the word, lesions 9 and 11 do not actually come under the head of the agraphias, because the agraphias here depend only upon a paralysis of the arm.

Therefore, only lesions 12 and 14 are to be considered as isolated, pure agraphias, and they can be distinguished one from the other by the retention of the power of copying in 14, and its loss in 12.

¹ It is better to limit the terms alexia and agraphia to the disturbance of written speech, which, in the usual acceptation of its term, are independent of aphasia. As literal disturbances of written speech they may be contrasted with verbal disturbances due to aphasia, since Wernicke (*Das aphasische Symptomcomplex*, Deut. Klinik, 1906) has shown that just as reading and writing among European folk occur by spelling, so disturbances of reading and writing affect not merely words, but also letters.

² The numbers correspond to those in Fig. 438.

The three alexias, 8, 10, and 13, can be differentiated one from the other by the fact that in 13, as opposed to 8 and 10, copying is retained, and that in 8, as opposed to 10, spontaneous writing is retained.

The forms of isolated alexias and agraphias, considered here theoretically, have thus far rarely been observed as pure cases, but much more frequently there occur *mixed forms* arising from diffuse injuries to the cortical mechanism of speech writing or from the combined injury of two or even more of the opposite convergent tracts in the neighborhood of the decussation angle. For this reason, and on account of incomplete interruptions of conduction, a local diagnosis of alexia and agraphia disturbances often becomes very difficult or even impossible.

Only two of the isolated alexias and agraphias have attained a sure place in clinical medicine, namely, the form of pure alexia referred to at 13, Fig. 438, p. 1108, and the combination of alexia with agraphia according to disturbances 13 and 14 of the text. If we start from the optic writing center α , they should be termed *trans-central*, but if, as Wernicke prefers, we start from the center of tone speech, they should be called *subcortical* or *subcentral*. These two types have been so carefully studied, both anatomically and clinically, that we are able to evolve the *anatomic nature of the mechanism of writing and reading*.

Fig. 442.—Lateral view of the left cerebral hemisphere according to Dejerine. The zone of language is shaded; *B*, Broca's convolution, seat of motor word-image; *A*, Wernicke's convolution, seat of acoustic word-image; *Pc*, pli courbe, gyrus angularis, Dejerine's seat of optic word-image (see text).

Whatever has been said concerning the mechanism of writing, in the region below the line *ab* of Fig. 438, p. 1108, and the isolated literal alexias or agraphias, i. e., those independent of aphasia, has only a theoretic value, because the author's diagram of the central mechanism of writing is purely theoretic. But, just as in the explanation of true aphasia, it now becomes necessary to ascertain the anatomic meaning of the centers $\alpha\beta$ and the association tracts, $\alpha\alpha$, $\beta\alpha$, and $\alpha\beta$ of Fig. 438. According to Fig. 437, p. 1107, we may assume that the point β in the anterior central convolution is the motor center for the usual manner of writing with the right hand, and that it can be replaced by any other motor center if other parts of the body be used for writing. As we have already (p. 1107) dispensed with an actual center for writing, it is evident that the path, $\beta\nu$, is simply the corresponding motor pathway, i. e., the pyramidal fibers belonging to the right arm. Moreover, the whole question hinges on the conception of the center α . The typical symptom-complex of isolated or literal alexia or a combination of literal alexia with agraphia, without essential disturbances of speech, is regularly associated with lesion of the left temporal lobule, especially the gyrus angularis. It was, therefore, most convenient to assume, with Dejerine, that an isolated optic word center existed in the left gyrus angularis, a

lesion of which, or its dissociation from the other speech apparatus, would cause this symptom complex. Fig. 442 shows this localization according to Dejerine's conception.

This conception is altogether untenable, since, as we have seen on p. 1108, written speech is represented in the cortex, not as entire optic word-memory pictures, but rather as letter images. In reading, the function of the organs of internal speech is to construct these letter images as (acoustic) word concepts. In writing, a series of optic letter concepts is reproduced through the disintegration of the word conceptions. If, therefore, an optic center in the left hemisphere must be assumed, it can only be a center for optic letter images. But we must follow Wernicke further in the criticism of this view, and deny the existence of a left-sided optic speech center altogether, even though it be for letters only. We have sure proof, from observations on right-sided hemiopia, that optic letter memory pictures are deposited in both hemispheres, and that they behave just as other memory images do. If optic letter memory pictures were deposited in the left hemisphere only, as one was inclined to deduce from cases of isolation alexia and agraphia, alexia must necessarily appear in right hemiopia caused by interruption of the left optic tract, the left hemisphere obviously being blind. We know, however, that this is not the case, not even temporarily. Hence the excitation from the right hemisphere must be sufficient to arouse optic letter images in reading, and to associate them with the organs of central speech. This obviously depends on the fact that the fixation-point is represented in both hemispheres, and that central vision hardly suffers at all in hemiopia. The assumption of a peculiar and individual optic speech center, in the sense of an optic letter center α in the left hemisphere, Fig. 438, is purely fictitious for the sake of easy comprehension, and Dejerine is not warranted in according it an anatomic position. As a matter of fact, to explain isolated alexias and agraphias, we must consider α as two centers, placed symmetrically on either side of the middle line, in the optic region, *i. e.*, occipital lobes of the left and right hemispheres.

But how do the anatomic findings mentioned above, *i. e.*, lesion of the left angular gyrus, which produces isolated alexia, create the impression of a left-sided optic speech or letter center? Obviously, because the letter memory pictures,¹ have of themselves no meaning, and acquire importance only through association with the acoustic letter or sound concept, *i. e.*, the acoustic speech center, which is localized exclusively in the left side. We, therefore, conclude that the occurrence of alexia in lesions of the left gyrus angularis is in no way due to the fact that the ideas of letters are disturbed (this is impossible, because, as we have seen, the optic letter memory pictures are stored in both hemispheres), but is due to an interruption of the association of these optic letter memory pictures with the acoustic speech center of the left side. The anatomic conditions of the white matter of the gyrus angularis are such that a lesion may have this effect, as Fig. 443, p. 1116, will show. According to the figure, the white matter of the temporosphenoidal lobe, including the gyrus angularis, contains three principal fasciculi, namely, the fasciculus longitudinalis inferioris, which connects the cortex of the temporosphenoidal lobe or the acoustic word center, with visual center of the occipital lobe; the callosal fibers, which connect the acoustic word centers of the left side with the right temporal and the right occipital lobes; and the optic radiations, passing from the posterior border of the internal capsule to the visual center of the occipital lobe on the same side.

According to von Monakow's and Wernicke's investigations, these fasciculi appear in close contact at the point (lesion y , Fig. 443) where pure alexia is usually localized. A lesion at this point, therefore, interrupts, first of all, the left optic radiations, and by isolating the left hemisphere, *i. e.*, the left depot for letter memory pictures, from the external world causes the right temporal hemiopia that has so far always been associated with alexia. Consequently, in attempting to read, this source of apperceptions becomes closed. Normally, however, there remain the stimuli from the right occipital lobe, which reach the acoustic word center by means of the optic acoustic callosal commissural fibers. (See Fig. 443.) The lesion y interrupts this pathway also, and the acoustic word center is thus closed to every sort of optic stimulus. As a result, we have alexia. The lesion y corresponds in its

¹ It would be really better to speak of optic oculomotor letter memory images, because the essential characteristic of optic letters is the representation of the linear direction taken by the letters. As the cortical area of the opticus stands in close interrelation with the motor centers of the ocular muscles, this feature must depend on the association of the image with the representation of ocular movements belonging to it.

effect to lesion 13 of Fig. 438, p. 1108, and it is designed to show, unnecessarily perhaps, that, in addition to the left optic radiation, there is interruption of the association between optic and acoustic centers of the left side (fasciculus longitudinalis inferioris) as well as the connection between right and left auditory centers (bitemporal callosal commissure). Although this adds nothing to the clinical picture, it is conceivable that in rare instances the symptom-complex of alexia may occur without destruction of the optic radiations, i. e., without hemiopia. Thus it might happen that merely the connection between the left temporal lobe and both occipital lobes (fasciculus longitudinalis inferioris of the left side and the optic acoustic callosal fibers coming from the right side) was destroyed. In this instance, the acoustic word center would still be closed to all optic stimuli. It should be mentioned that lesions of the left gyrus angularis causing pure alexia occur, as a rule, through embolus of the posterior twig of the third branch of the Sylvian artery.¹

Blindness for musical notes has also been observed as another detail of the clinical picture of pure or literal alexia. (See p. 1123.) By this is meant the addi-

Fig. 443.—Diagrammatic representation of literal alexia and agraphia. Lesion *y* causes pure alexia; lesion *x*, alexia with agraphia; *NC*, nucleus caudatus; *Nl*, nucleus lenticularis; *Th o*, optic thalamus. The structures concerned in literal alexia are represented diagrammatically by a horizontal section through the superior end of the fissure of Sylvius.

tional loss of the comprehension of musical notation and the ability to sing by note; it is really alexia for musical notation.

The cases of alexia which we have thus far discussed have not been associated with agraphia, because the communication between the motor speech center, the depots for optic letter memory pictures (of both hemispheres), and with the motor center of the right hand, has been preserved. It has been occasionally observed that patients are able to overcome or avoid alexia by carefully tracing the letters with the finger. This enables them to read aloud with comprehension. In this instance the mechanical act of copying reverses the process of voluntary writing, and thus awakens the idea of the word (from *a* to *b*, Fig. 438, p. 1108). Magnan has described a case of isolated alexia which had the remarkable peculiarity that the patient was unable to read, either by sense of touch or by the optic tract, although raised letters were employed, on account of lack of practice with letters used by the blind. It is explained by an interrupted communication between the tactile

¹ See von Monakow, *Gehirn-Pathologie*, Nothnagel's *Sammelwerke*, 1897, p. 673.

representations (most probably located in the central convolutions and the parietal lobe) and the acoustic speech center. The ability to find the right word is commonly involved in isolated alexia, to such an extent that it resembles aphasic disturbances and may lead to a false conception of the case. In the latter instance this depends on the fact that there is not only a disturbance of the association of the letter image with the acoustic word image, but also the association of other (objective) optic impressions with the entire acoustic speech center. (Relation of Alexia to Optic Aphasia, see p. 1119.) As we take the ground that the optic letter memory images are in no way different from the other optic memory pictures, this is perfectly clear. For the same reasons, it is quite evident that so-called pure alexia may be associated occasionally with a certain degree of psychic blindness, because the left hemisphere has already been deprived of the impressions (through the hemiopia), whereas the right hemisphere has lost although not completely, the most important association paths for the recognition of objects, *i. e.*, for word conceptions. From this detailed description of the symptom-complex it is evident that its designation as pure alexia is to be taken *cum grano salis*, and only signifies that it is an alexia not dependent on a primary disturbance of acoustic speech. When the disturbance at the point *y* (Fig. 443) is incomplete, or when there is only a functional disturbance due to the remote effect of a lesion in the vicinity, instead of alexia, we observe the clinical picture of dyslexia, *i. e.*, difficulty in reading with rapidly appearing fatigue, which often leads to complete inability to read and a consequent disinclination to read on the part of the patient.

In addition to the so-called isolated alexias, the combination of alexia with agraphia is practically the only disturbance of written speech among the theoretic possibilities considered (p. 1113), due to a lesion of the arc of writing (Fig. 443), rather than to a disorder of spoken language. A glance through the literature will show that in these cases also lesions in the gyrus angularis are found. According to Wernicke, however, they differ in that the lesion is more extensive than in the former, and approaches the cortex more closely, as lesion *x* (Fig. 443) will show. The appearance of agraphia in these cases is to be explained by the theory that, in consequence of the greater extent and less circumscribed position of the lesion, either the pathway which connects Broca's center with the optic center (Fig. 438, p. 1108), or else the tract between the optic center and the motor center for the right hand (*aβ*, Fig. 438) must be destroyed. In the second case, the patient could still write with the left hand, whereas in the first the ability to write would be lost for all parts of the body.

We know very little as yet concerning the anatomic character and position of the tracts assumed to be involved when agraphia appears, and the author has purposely refrained from indicating them theoretically in Fig. 443. The disturbances of writing and reading in this combination differ from the disturbances of written speech, which accompany true aphasias, in that verbal disturbances, *i. e.*, writing and reading of words, are not more predominant than the literal disturbance, *i. e.*, writing and reading of letters. Thus, for example, letters cannot be copied mechanically, as they are not recognized, and cannot be transposed from one style to the other. But if we except mechanical copying even the true aphasic, under certain conditions, *i. e.*, severe verbal disturbances of writing and reading, cannot always do this.

By means of these clinical pictures we can understand the anatomic nature of the diagram of writing (*αναμβν*, Fig. 438), but the position of the tract *aβ* is still an open question. A lesion of this tract (lesion 12 in Fig. 438) should cause isolated agraphia. But since, as far as the author knows, such a case without alexia and without aphasia does not exist, no definite assertion may be made concerning its position. Von Monakow considers it probable that the fasciculus longitudinalis superioris of the cortex contains the association fibers between the optic centers for letters and the motor region, although this is purely hypothetical. That isolated agraphia has never been observed is probably due to the fact that the tract *aβ* is placed bilaterally, corresponding to the bilateral deposition of letter images, and hence a unilateral lesion cannot disturb this function. This leaves quite out of consideration the fact that each optic center is not merely associated with both hands, but with multiple motor tracts, as we can write with every part of the body (Fig. 437, p. 1107).

Wolff has described a curious form of combined alexia and agraphia without aphasia in which there was a double cortical blindness. The patient could neither write nor read, since both of the optic zones were destroyed, the first because of blindness, the second because the letter concepts and all their associations were disturbed.

Although reference has been made in the preceding paragraph to the absence of

agraphia without alexia, cases *resembling* pure agraphia are really not so uncommon. A careful history, however, will very soon show that they are really the vestiges of a receding aphasia. In fact, an isolated residual disturbance of writing is not at all uncommon during recovery from a central motor aphasia (Broca's), at the time when the speech faculty is either completely or almost completely restored (in these cases we are probably dealing with remote effects without actual destruction of the centers, or with the assumption of function by the right hemisphere seen only in children). The reason for this lies in the fact that the motor speech center has recovered the easier function of speech, whereas the more difficult act of writing (more difficult because the impulses must pass over a greater number of neurons) is still defective. Without proper histories, these cases may very easily give the impression of independent agraphia; but it is just in these cases of mild functional disturbance, rather than complete destruction of Broca's center, that the verbal, and not the literal, character of the agraphia is demonstrated by examination. For such apparent isolated agraphia, the author would suggest the name *aphasic residual agraphia*.

The Mixed and Unclassified Forms of Aphasia; Functional, Amnesic Aphasia.—The Real Nature of Transcortical Aphasia.—It should also be noted that the diagnosis of individual cases is often made very difficult in aphasias by the occurrence of such mixed forms from lesions of the converging tracts, as well as by the occurrence of incomplete lesions of individual tracts and centers and of diffuse lesions. Hence every case of aphasia cannot be tabulated under one or the other of the above types; at all events, not without much difficulty.

There is still another reason why, practically, aphasias are often more difficult to explain than one would judge from our simple diagram. For in addition to the above-described type, where the disturbances depend upon injuries to tracts and destruction of centers, there is still another group of aphasias in which the difficulty is merely functional in nature and the tracts and centers in question are not actually destroyed or even injured. Such aphasias depend upon a very difficult or an imperfect innervation of the center and tracts upon the part of the patient. From the nature of the trouble, the clinical picture not only varies so conspicuously as to make a local diagnosis difficult, but also presents many other peculiarities. Under this head come the aphasias which are attributed to a disturbance of the memory, as the following case of Grashey will illustrate. This patient could give the name to an object held in front of him only so long as he was looking at it, and even then only while he was writing down its name and thus aiding his memory. These aphasias from disturbances of memory have been considered fundamentally different from the other aphasias, but the author cannot agree with this view. For what do we actually understand by a disturbance of memory? Apparently, on the one hand, only a difficulty in voluntarily recalling certain latent memory pictures, i. e., a difficulty in associations, and, on the other hand, an abnormally rapid fading of concept soon after their origin. Between these conditions and a complete destruction of the association fibers or of the concept centers there is only a difference in degree. Such destructions depend upon appreciable anatomic lesions, while disturbances in memory are to be attributed only to slight functional damage to the same centers and tracts.

By adhering to this definition of disturbances of memory, we can term these functional aphasias *memory aphasias* (in Grashey's sense), in contrast to aphasias from destructive lesions.¹ The former, however, include not only Grashey's and similar cases, but, as will be easily understood, most of the transcortical and especially the complete transcortical aphasias. In a complete transcortical motor aphasia, which is the direct consequence of a gross anatomic lesion, all tracts which lead from *a* and *b* in Fig. 434 to the partial representations of the idea must be interrupted. But since these partial representations of the idea are spread out in the entire cortex, we must assume that the fibers *bc*, *bc'*, *bc''*, etc., in reality extend in all directions from the speech centers (Fig. 439). A complete interruption of conduction of these collected tracts could then be imagined only if the centers, *a* and *b*, were to a certain extent isolated, as by a ring-shaped lesion. However, in assuming a gross anatomic lesion, it is quite impossible that the centers *a* and *b* could remain intact, so that symptoms of a central instead of a transcortical aphasia must result. It is, therefore, evident that complete transcortical motor aphasia and, for similar reasons, even a

¹ Central and transcortical aphasias, dependent on anatomic lesions, in which difficulty of finding words simulates memory weakness, should not be confused with amnesic aphasias due to disturbances of memory or function. The cause of this phenomenon is different and depends on the fact that the word cannot be found or spoken, because the impulses travel only the path *Cb* and not *Cab* at the same time.

transcentral sensory aphasia, cannot arise from direct gross anatomic destruction of all the transcentral tracts. A complete anatomic destruction of the latter is absolutely impossible without a lesion of the center *b* or of the center *a*.¹ But from what has been said, it is easy to understand that these transcentral disturbances may result from those functional lesions defined above as disturbances of memory.

Such a functional disturbance may, of course, be diffused not only to the tracts of the speech mechanism, but also over the entire brain. In the former case merely a memory disturbance of speech will result; in the latter, a general weakness of memory and intelligence, of which the aphasia is only a part.

Most of the disturbances of speech called *indefinite* or *diffuse aphasias*, as contrasted with the definite accompanying functional lesions. They include aphasias which can be explained, not by a lesion at definite places in the scheme, but only by the assumption of a disturbance diffused over the territory of the speech apparatus. Such aphasias usually present an exceptionally variable character, and so cannot be attributed to the direct action of gross anatomic disturbances, although anatomic mixed aphasias may have the character of a diffuse aphasia. (See p. 1118.)

It should, however, be noted that in designating certain aphasic disturbances as *functional*, we do not mean that they cannot occur from the remote action of gross anatomic lesions. On the contrary, indefinite and transcentral aphasias, which, according to the above definition, must be considered as functional, generally exhibit lesions in the neighborhood of the speech centers. There is no actual destruction of brain substance in a gross mechanical sense, but the lesion indirectly causes a functional disturbance of the speech apparatus from *remote action*. This remote action, playing so important a part in other parts of the cerebral pathology, is, as is well known, to be attributed partly to the results of circulatory disturbances, partly to inhibition.

Although most transcentral aphasias can thus be considered as functional, or, in the sense above, as of an amnesic nature (arising from weakness of memory or of association), such a grouping does not necessarily include those transcentral aphasias in which not all the transcentral tracts uniting the conceptual part of the brain with the speech center, but merely a certain number of transcentral tracts of separate function, are affected. To this class belongs Freund's so-called optic aphasia, in which the patient cannot name objects after he has received their optical impression. Here we must assume an isolated lesion of the fibers running from the visual center to the motor speech center. Such a lesion may be anatomic as well as functional. In the cases described up to the present, however, a coincident hemiopia, has always been found, and sometimes even word-deafness. In the examination of optic aphasia, psychic blindness should always be looked for at the same time, because optic aphasia may be merely an associated symptom of general psychic blindness (p. 1123). One must also determine whether or not the patient recognizes objects by sight. Up to the present time the anatomic findings in optic aphasia have regularly revealed lesions in the white matter of the left occipital lobe. This is easily understood, since an interruption between the motor speech center and the optic partial concepts must be the cause of the symptom-complex. Concerning the relations between optic aphasia, alexia, and psychic blindness, see p. 1123. The terms *acoustic* and *tactile* aphasia have meanings analogous to that of the expression *optic aphasia*.

Finally, it may be mentioned that in aphasia, numbers are effected like other words only when they are spoken, not written. Numbers expressed in figures occupy a peculiar place in written speech, because no real word concept of them occurs either in writing or reading. The figure is a direct symbol of the notion of counting; to a certain extent, a hieroglyphic. Its optical representation probably may be considered as directly associated with the conception (Fig. 438). Hence, even when the word concept in aphasia is destroyed, the patient can write figures quite well and can understand written figures.

For the explanation of *anarthria* as a result of incomplete aphasia, i. e., of incomplete lesions of the central speech apparatus and of receding aphasias (central anarthria), p. 1101 et seq. may be consulted. In another type of incomplete aphasia the difficulty is limited to certain definite words. These are forms in which ordinarily no definite location in the speech mechanism is possible, and which usually come under the head of the functional or diffuse disturbances (p. 1118).

Criticism of P. Marie's Conception of Aphasia and the Disturbances of the Intelligence in Aphasia. The Author's So-called Logasthenia (Mihi).—P. Marie,² through ob-

¹ As we shall see below, it must be acknowledged that transcentral aphasias may arise directly from gross anatomic lesions by so-called remote action.

² Sem. méd., 1906, No. 21.

jections that are neither new nor, in the author's opinion, valid, has recently sought to overthrow the doctrine of aphasia given in this book, and the one generally accepted in Germany. This work is based on the well-known fact that, in a few isolated cases of central or cortical aphasia, no lesion of Broca's center has been found, and that, conversely, no aphasia followed a lesion of this area. This leads him to contest the localization of the motor center of speech in Broca's area. A refutation of Marie's arguments will be found in Naunyn's exposition of aphasia at the Medical Congress for Internal Medicine, 1889. He has shown that the greater part of these cases were not examined carefully enough, and that certain of them, showing Broca's area to be intact, were either not cases of this form of aphasia, or else were to be explained by a functional disturbance of the right hemisphere. Schreiber has shown that not merely left- but right-handed individuals as well, may have the aphasic lesion in the right hemisphere. Naunyn also points out that absence of aphasia following a lesion of Broca's area might be due to the fact that the speech center was situated in the right hemisphere. Certain it is that such apparently exceptional cases should be examined microscopically before they are accepted, since it is well known that decided hemiplegias occasionally show no macroscopic lesion in the brain. Furthermore, Naunyn's graphic record of the great number of cases in which the preponderance of probability places the location of the motor speech center in Broca's area, and that of sensory speech in Wernicke's area, furnish important evidence against Marie. The latter, relying on the exceptional cases which do not overthrow the rule by any means, removes with the stroke of a pen Broca's center, one of the landmarks of medicine that we have hitherto regarded as one of the greatest achievements of science. Marie reaches the following remarkable conclusion: that there is merely one kind of aphasia, although it is capable of great quantitative variations. It is localized in Wernicke's area and its distant and immediate vicinity, and consists essentially in a diminution of the intelligence necessary to speech. In the severest cases, this disturbance is so great that there results a complete lack of comprehension of spoken words, *i. e.*, the picture of Wernicke's sensory aphasia. In milder cases the defective intelligence is revealed only in a difficulty of comprehension, so that the patient can understand and execute simple uncomplicated commissions alone. He attempts at great length to prove that these disturbances of the comprehension of speech are really due to defective intelligence, by arguments based on the well-known fact that aphasics always exhibit some defective intelligence. The various forms of aphasia, to the establishment of which we owe so much to Lichtheim, Marie considers as merely higher or lower grades of this defect of intelligence, and maintains that their variations cannot be more closely analyzed. This is a statement which may be absolutely refuted by the fact that a great number of these cases can be sharply differentiated. Marie designates severe disturbances or loss of motor speech (motor aphasia) as *anarthria*; but if, in addition to this, there are sensory manifestations, *i. e.*, "defective intelligence" he calls the condition aphasia complicated by *anarthria*, and refers it to a lesion of the lenticular region [*zone lenticulaire*.—Ed.] This jumbling of motor aphasia and *anarthria* appears absolutely unjustifiable to the author; especially the localization of *anarthria* in the lenticular region. The author believes that Marie's doctrine indicates a decided step backward, and that it should not be accepted rashly; furthermore, that we are not justified in drawing the far-reaching conclusions from the exceptions to Broca's localization in central aphasia that Marie does, since these exceptions may be explained differently. The disturbances of intelligence, so constant in aphasia (even of the motor type), were recognized long ago and cannot be denied. But it does not necessitate the conclusion that it is the cause of the aphasia, and that the latter is merely a result of a peculiar form of defective intelligence, for it is perfectly obvious that the latter may result from the aphasia. All our higher processes of thinking take place in the form of interior language, as every one may demonstrate on himself, and it is very probable that they suffer considerably from the speech defect. To the author, it seems likely that the patients in whom these peculiar psychic defects arise, as a result of the speech disturbance rather than the cause of the same, appear not exactly idiotic or stupid, but in the condition of highly intelligent animals, capable of emotions of a finer type, even of reasoning power, in spite of the lack of speech, but who, on account of the lack of interior language, are without certain higher psychic functions. The author suggests that, since this higher faculty of thinking, which is associated with interior language, is peculiar to man, and is the chief point of differentiation between the animal and human mind, it should be called *logos*, and a disturbance of it, *logasthenia*. In the author's opinion, it is a result and not the cause of aphasia. This is supported by the fact that, as the interior language is undisturbed in subcentral or subcortical forms of aphasia, there is

no logasthenia. The greater relative frequency of the so-called unclassified aphasias—i. e., those that cannot be sharply localized according to the Wernicke-Lichtheim scheme—is no argument against the correctness of the author's psychophysical and psychopathologic plan; on the contrary, if we consider the ultimate physiologic connection of all the widely separated parts of speech mechanism, it is not difficult to understand.

For further details, the discussion on Marie's conception of aphasia in the Société de Neurologie de Paris (Revue Neurologique, 1908) should be consulted.

(c) Other Speech Disturbances from Paralytic Phenomena

Anarthria and aphasia are the best known and the best studied of the disturbances of speech resulting from paralytic phenomena. There are, however, a number of other speech disturbances to be regarded as paralytic phenomena which are not yet exactly explained and, in fact, cannot be definitely localized.

The disturbance of speech in *progressive paralysis*, which is characterized by syllable stuttering, belongs to this class. From its peculiarities it belongs rather to the anarthrias than to the aphasias, and is ordinarily so classed; but it is questionable whether such a classification is correct. The well-known anatomic localization of progressive paralysis in the cerebral cortex makes it most probable that the speech disturbance is also cortical. Such a conception of its origin would suggest a closer relation to the aphasias, despite the external difference, and, according to the classification on p. 1101, it must be called central anarthria. As a matter of fact, such a disturbance of speech may perfectly well be conceived to arise from minute lesions in the area of the speech center, by which speech coördination is destroyed, although a complete paralysis of the center does not result. Perhaps the disturbances of speech in intoxicated persons may be similarly explained. Without doubt the *hysteric speech disturbances*—hysteric aphonia (improperly called hysteric vocal-cord paralysis) and hysteric mutism, should be localized in the cortex, and, therefore, despite clinical differences, are closely related to aphasia. *Congenital dumbness* is nothing more than motor aphasia, and deaf-mutism is sensory aphasia plus motor aphasia plus deafness. The imperfect monotone speech which deaf-mutes can be taught may be considered as a form of speech arising, with sensory aphasia, by arduous and unusual paths, in which, instead of the entire word concept $a + b$, there is only available a motor word representation. The different disturbances of speech of those who are seriously ill (the vibrating, tremulous, slowed, and abnormally faint speech) have not as yet been definitely localized. They may be central as well as peripheral. The characteristic scanning speech of *multiple sclerosis* and the speech defect of *Friedreich's ataxia* do not yet possess a definite significance. The former, perhaps, may be regarded as a sort of spastic gait of the speech. As a result of the increased muscle and tendon reflexes, which may frequently be demonstrated in the muscles of speech in this disease (jaw-clonus, etc.), the speech movements are mechanically hindered by the occurrence of spasms of the muscles, which the patient instinctively tries to overcome by slowing his speech and accentuating its movements. The monotone and the lack of the ability to modulate the voice may also be explained by such spastic phenomena. Ordinarily, the speech does not become tremulous, as do the other spastic movements, although a tremor may sometimes be observed as a result of quivering contractions of the vocal cords. This is probably due to the fact that the muscles of speech run in all the directions of space, and that tremors can be produced only by the alternate activity of antagonistic muscles, the lines of whose action are situated in the same plane.

3. AFFECTIONS OF SPEECH FROM IRRITATION PHENOMENA

These irritation or spasmodic phenomena in the territory of the speech apparatus have been much less studied than the speech disturbances thus far described, and which we have considered paralytic.

They include the commonest varieties of stuttering (labiochorea and guttural tetanic stuttering), both of which are sufficiently defined by their names. They also include the affections of speech in chorea. It is not yet clear how these disturbances arise, nor is it known from what point the impulses spring, although they probably have a cortical localization. It is not necessary to assume that they come from the speech center. This would be at variance with the conception of chorea on p. 959. For, as the speech muscles are not utilized exclusively for speech and are not innervated exclusively by the speech center, it is easy to understand that choreic movements of the speech muscles might arise from other parts of the cortex and still affect the speech. The tracts concerned in this are mentioned on p. 959.

4. PLAN FOR TESTING THE FUNCTIONS OF SPEECH

The following plan for examining patients with speech disturbances has been devised from what has been said above:

1. Disturbances of pronunciation of letters and then of simpler and more complicated words. Anarthritic disturbances of bulbar paralysis; speech disturbances of progressive paralysis; of multiple sclerosis; stuttering, etc. For the differential diagnosis between pure anarthria and what is called on p. 1102 "central anarthria," it must be noticed whether disturbances other than those of speech (swallowing, masticating) occur in the region of the speech muscles.

2. In the actual aphasic disturbances the following functions should always be examined:

(a) TEST FOR WORDS

1. Voluntary speech. Examination for naming and paraphasia (word confusion).

2. Repetition.

3. Reading aloud.

4. Voluntary writing (figures to be tested especially) (p. 1119). Examination of written paraphasia (word confusion in writing).

5. Writing from dictation (figures to be tested especially).

6. Copying.

7. Speech comprehension.

8. Script comprehension (figures to be tested especially).

9. Counting syllables. (See p. 1106 et seq.)

It is usually better in complicated aphasias to test sensory speech first, since in judging the motor speech function one should know (especially in repetition and syllable counting) whether the tone images are formed or how much the patients understand.

(b) TEST FOR LETTERS

1. Speaking the letters of the alphabet spontaneously with special attention to the quality of the pronunciation.

2. Repetition of letters.

3. Reading letters aloud.

4. Writing the alphabet spontaneously.

5. Writing letters from dictation.

6. Copying letters.

7. Recognition of spoken letters, *i. e.*, association of the sounds with the pictures of letters (picking out the corresponding printed letters).

8. Recognition of written or printed letters, *i. e.*, association of the letter pictures with the spoken letters (where the letters cannot be named, suggestive questions should be used in the test).

For the sake of localization one must ascertain whether the patient was right or left handed.

Since paralysis of the right arm is very commonly associated with aphasia, the patient's ability to write with the left hand should be tested (many aphasics produce mirror-writing). If the patient cannot write with the left hand, he should attempt to construct the words with letters such as are used in the ordinary game of anagrams.

If every case of aphasia is examined according to this plan, it is easy either to localize the aphasia at one or more definite points of the speech mechanism, or to determine that it is caused by an indefinite, *i. e.*, a functional or diffuse injury of the speech mechanism.

Finally, we should remember that these patients very rapidly become fatigued in performing the almost superhuman tasks that such an examination entails for them. Whenever this point is reached, it is better to discontinue the examination, for otherwise it becomes a useless torment, causing an aphasia which might be definitely localized to become so diffuse and indefinite as to lead one to false conclusions. This may readily be understood if we bear in mind that normal individuals may exhibit certain aphasic phenomena (misstatements, difficulty in naming, mild anarthric disturbances) during excessive cerebral fatigue. [Bonhoeffer¹ and Koch² have shown that the peculiar paraphasic utterances, so frequently seen in these states, are due to disturbances of the attention, and that they are most marked when the latter is

¹ Die Geisterstörungen der Gewohnheitstrinker, Gust. Fischer, Jena, 1901.

² Drug Deliria, Review of Neurology and Psychiatry, Feb., 1906.

at a low level. As it is well known that fatigue affects the attention very rapidly, and thereby increases the tendency to paraphasia even in normal individuals, we can easily see how a prolonged examination may intensify the aphasia and thus obscure the actual degree of speech disturbance.—Z.]

The symptom of "*perseveration*" (Neisser) may often be demonstrated in the examination of an aphasia. It consists in an inclination on the part of the patient to repeat the reaction when once it is found, even if he know he is saying or doing something incorrectly. There exists a certain amount of compulsion in this, which probably depends on the principle of the inclusion of the pathways. The patients themselves often become impatient.

VII. DISTURBANCES RELATED TO APHASIA ; ASYMBOLIA ; AMIMIA ; APRAXIA ; AMUSIA ; PSYCHIC DEAFNESS ; PSYCHIC BLINDNESS

Asymbolia is a condition of the mind in which the ability to make one's self understood by signs and gestures (as well as by speech) is impaired or lost. A differentiation may be made between active or motor and passive or sensory asymbolia, dependent upon whether pantomimic speech or the ability to understand it is affected.

Amimia is a disturbance or loss of the power of imitation, whether it be simply the mimicry associated with speech or the mimicry expressing psychic processes.

Apraxia (Liepman) is the inability to employ objects in the proper way, the patient taking a spoon or fork in his hand, for example, and being unable to use it correctly.

The disturbances just described are also characterized by the fact that they are not associated with actual motor paralysis, i. e., with motor disturbances of the affected muscles for other muscular functions. The intimate relation between the functions above mentioned and the function of speech sufficiently explains the fact that these disturbances are found almost exclusively with aphasias, and that their localization is practically the same as that of aphasia. [A careful study of Marie's articles on aphasia will convince the reader that many of the examples of defective intelligence cited are in reality very good instances of apraxia.—Z.]

The loss of the ability to produce or comprehend music or musical sounds has been designated as **amusia**. From the definition, it will be seen that amusia may be either motor or sensory. Motor amusia is related to motor aphasia; it has a similar localization and is sometimes associated with it. Sensory amusia is related to sensory aphasia, with which it is not infrequently combined. Its presence is indicative of a lesion in the left temporal lobe. A special form of amusia, the loss of the ability to recognize the musical significance of notes or to sing or play from notes, has been designated as "*note-blindness*," and another form, in which the power to comprehend music has been abolished, has been rather inappropriately called "*tone-deafness*." The first corresponds to alexia both in its nature and probably also in its localization; the second corresponds to pure sensory aphasia.

Psychic deafness is a condition in which not only words, but all sounds, though heard and perceived as such, awaken no intelligent conception. This disturbance evidently includes sensory aphasia, and the relationship of the two conditions is shown by the fact that sensory aphasia or word-deafness is sometimes combined with psychic deafness or passes into the latter condition.

Psychic blindness¹ requires a more detailed description. By this term is meant that peculiar condition in which objects are seen but not recognized. In other words, in spite of retained optic perception (optic apperception), the association of optic impressions is no longer possible. It holds the same relation to blindness as does psychic deafness to deafness. Psychic blindness can be produced only by a lesion in the transcortical tracts of the visual apparatus, i. e., by a lesion in the association fibers of the visual center (see p. 1095), and is associated with lesions in the occipital lobes. Psychic blindness, alexia, and optic aphasia are closely related conditions, having in common, an inability to estimate by association optic impressions; the anatomic lesions are correspondingly similar.

As the retinal impression of one eye, on account of the semidecussation of the optic nerve, affects both hemispheres, it is probable that the visual representations upon whose associations with other representations depends the recognition of objects, are, unlike speech or word representation, localized in both hemispheres.²

¹ See Lissauer, Arch. f. Psychiatrie, vol. xxi.

² This was established on p. 1115, under consideration of the localization of letter memory pictures; also that central vision is represented in both eyes.

This will explain the fact that complete psychic blindness is never observed in a unilateral lesion of the brain. If one hemisphere be completely preserved, visual perception and representation are not only pictured, but also associated; although a certain degree of psychic blindness has frequently been observed in the cases of left-sided lesion which cause alexia. (See p. 1117.) The following figure explains diagrammatically the occurrence of psychic blindness from bilateral lesions of the occipital lobes. It is supposed to represent a horizontal section of the brain: *a* the left, *b* the right retina; *c* the left, *d* the right visual center; *ad* and *bd* the fibers of the right, *ac* and *bc* those of the left optic tract; *ec* and *fd* represent diagrammatically examples of association fibers between the optic centers and other parts of the brain upon the same side. These are, of course, not single, but run in countless directions to all regions of the cortex not associated with vision, in fact, from each center of vision to both hemispheres. Now, according to the above, psychic blindness may arise from lesions of the bilateral association tracts (*ec* and *fd*)—for example, from lesions *g* and *h*; but it is highly improbable that in both posterior lobes only the association tracts should be affected in this way. As a matter of fact, heretofore it has been found that the fibers of the optic tract or even the visual center itself are

Chiasma

Nucleus caudatus

Nucleus lenticularis

Thalamus opticus

Fig. 444.—Diagram to explain the simultaneous occurrence of psychic blindness and hemiopia from a bilateral lesion in the occipital lobe. Horizontal cross-section of brain: *a*, Left retina; *b*, right retina; *c*, left sight center; *d*, right sight center (see Fig. 424); *ad* and *bd*, fibers of the right, *ac* and *bc*, fibers of the left, optic tract; *g*, *h*, and *i*, lesions.

injured coincidentally with the association tracts upon the one side by a large lesion like *i*; whereas upon the other side a smaller lesion (*h*) may affect only the association tracts (and in contrast to the simplified figure those to both hemispheres) and not include the visual tracts or even the visual center.

A patient with such a bilateral lesion (*i* and *h*) presents clinically homonymous hemiopia, i. e., he is absolutely blind to objects whose pictures fall upon the left retina. He perceives objects with the right retinal half, but he cannot recognize them, because the association of the right visual center with the remainder of the brain is interrupted. It need scarcely be emphasized that all the associations of optic representations need not be destroyed in every case of psychic blindness, but that in many cases only certain of them fail, while others are retained. Thus, it is conceivable that a patient can associate the optical representation of a rose with the word representation of a rose, but not with the representation of the smell of the rose. Such examples of partial psychic blindness are undoubtedly not so very rare in the psychoses. But we ordinarily speak of psychic blindness in the narrow sense of the word, or of a total psychic blindness, only when so many associations of the optical representations are lost that the conception of the latter (see p. 1103 et seq.) can no longer be elicited, i. e., the object can no longer be recog-

nized. An interference with the association of the optic representation with the speech mechanism, which is a kind of partial psychic blindness, has been studied as a partial transcortical aphasia upon p. 1119, under the title of Optic Aphasia.

Complete psychic blindness frequently presents the clinical picture of mental confusion or insanity. Patients do not recognize objects at all, and behave in a most peculiar fashion. In certain characteristics they may behave like the blind, stumbling, for example, over objects which they may probably see but do not recognize. The condition is, therefore, often not very easy to diagnose, and in examining such a case the following plan may be adopted:

1. Examination of the apperception in order to differentiate from a simple visual disturbance or from blindness. To be tested are: refraction, visual field (determination of hemiopia), acuity of vision (this may be attempted with corrected refraction). Testing the visual acuity in psychic blindness naturally presents very serious obstacles, as the ordinary test objects, such as letters, etc., cannot be recognized. We are, therefore, usually obliged to make use of some artificial device, such as requiring the patient to name the number of black points upon a sheet of paper.

2. Examinations to determine whether visual representations exist. In this connection only the patient's statements about optical memory, etc., can furnish any information.

3. Examination of association of visual impressions. Recognition of objects by statement of the name or by demonstration of their use, reading (aloud and with comprehension), copying, drawing, voluntary reactions to optical irritation, power of orientation.

4. Examination of the association of visual representations. Drawing from memory, writing spontaneously, writing from dictation.

5. In differentiating psychic blindness from general confusion or insanity, it is necessary to determine whether the other perceptions, viz., those of hearing, smell, taste, as well as the sensory skin sensation, are properly associated, and to observe whether the patients deport themselves sensibly so far as their behavior toward visual sensations is concerned.

The diagnosis of actual psychic blindness is frequently very difficult, and is often impossible when complicated with marked diminution in vision, because conditions occur in all forms of diminished visual acuity which have this in common with real psychic blindness, that the significance of what is seen is disturbed merely because the visual impressions are not sharp enough.

Psychic blindness is not to be confused with *cortical blindness*. The latter affection is an actual blindness, a loss of the visual power, produced by lesions of the cortex, which, owing to the hemiopic distribution of the visual function in both hemispheres, must be bilateral.

VIII. SPINAL HEMIPLEGIA

Unilateral lesions of the spinal cord produce a symptom-complex which is known as "spinal hemiplegia," in the broadest sense of the word. This hemiplegia varies in character according to the location and extent of the lesion.

The *motor disturbances* appear in the extremity upon the same side as the lesion and in only the lower, or both the lower and the upper, extremities, according to the level of the lesion. The motor paralysis dependent upon an interruption of the long tracts, particularly of the pyramidal tract, is spastic in character, as in a complete transverse lesion of the cord, is associated with increased tendon reflexes, and is not accompanied by degenerative atrophy of the paralyzed muscles. If the lesion have a considerable vertical dimension, this spastic paralysis may be associated with a degenerative atrophic flaccid paralysis due to involvement of the nuclei in the anterior cornua. With an extensive vertical lesion in the cervical enlargement, for example, the spastic paralysis will be bounded above by a degenerative flaccid paralysis of the upper extremity; if the extensive vertical lesion be situated in the lumbar cord, the paralysis of the muscles supplied by the injured segments will be atrophic and relaxed. Should the lesion involve the entire length of the lumbar swelling, the spastic paralysis of the leg will be entirely replaced by a flaccid degenerative paralysis. In reference to the spastic components of the paralysis dependent upon the involvement of the long tracts, it may be said that the laws given for cerebral hemiplegia on p. 1088 et seq., in reference to the more or less marked involvement of the individual muscle groups, also obtain in spinal hemiplegia.

The *vasomotor* tracts are involved upon the side of the lesion, so that the extremity at first seems warmer than its fellow of the opposite side. This difference sub-

sequently becomes equalized by the decreased heat-production in the paralyzed muscles, and also by the disappearance of the vasomotor palsy as the result of the vicarious action of deeper centers. The paralyzed side may then even be colder to the touch than its opposite fellow.

The *sensory disturbances* in unilateral spinal lesions are of special interest and somewhat more complicated. We have just seen that the motor symptoms, corresponding to the uncrossed exit of the motor tracts from the spinal cord, occur only upon the same side as the lesion; but the sensory disturbances are partly bilateral,

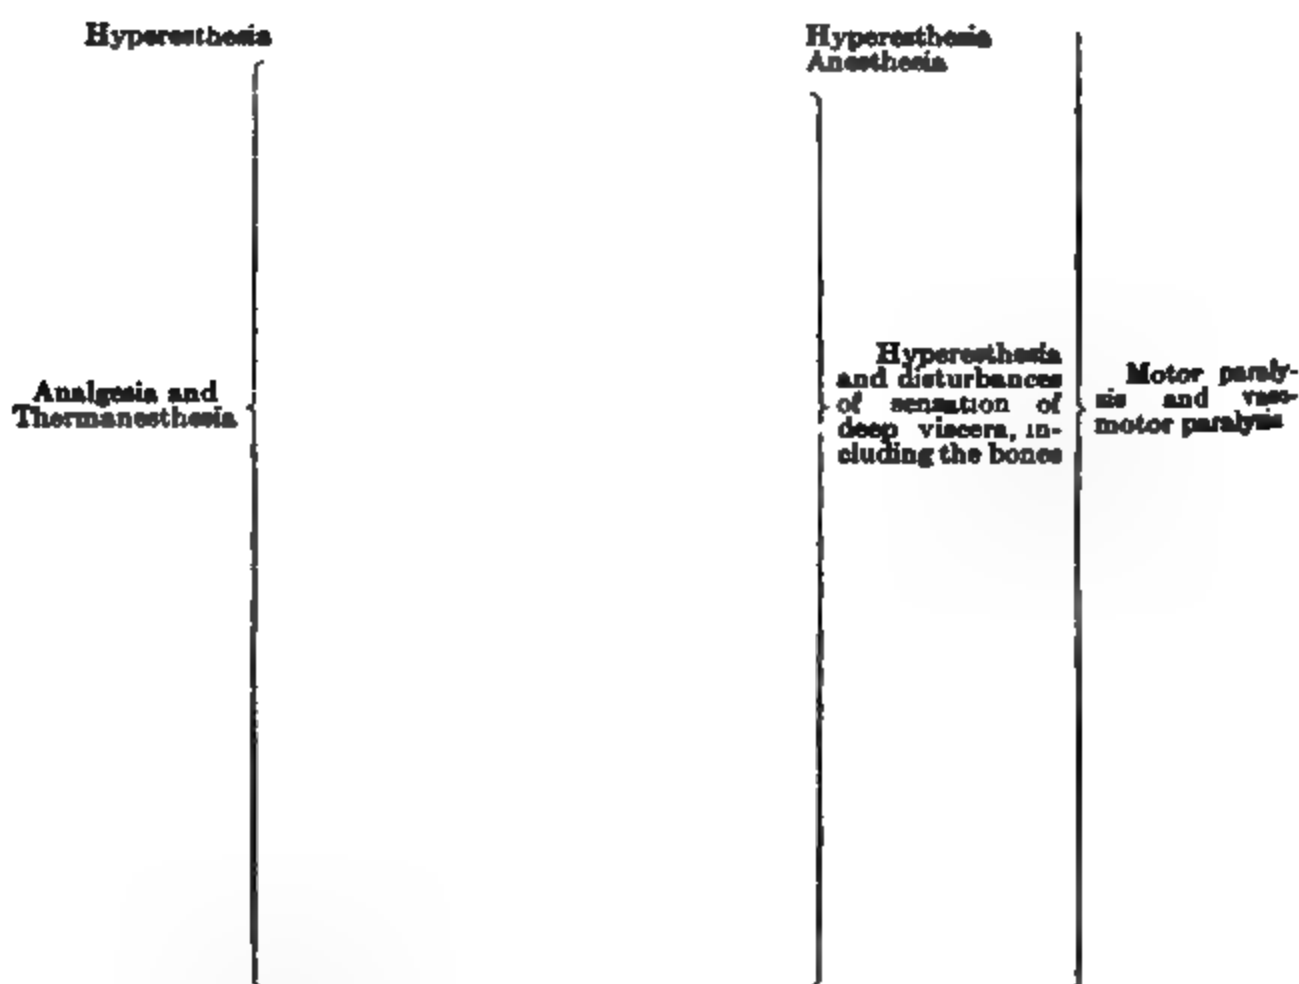

Fig. 445.—Spinal hemiplegia. Lesion upon the left side of the patient. Type 1: Motor and vasomotor paralysis. Varying degree of disturbance of sensation of the deep viscera (perception of position), including the bones.

. Cutaneous hyperesthesia to touch (also in the red shaded area).

Complete cutaneous anesthesia.

In the white areas there is neither motor nor vasomotor paralysis.

although most of them are present only upon the side opposite to the lesion. The observation of the sensory phenomena in such cases has resulted in the establishment of the three following types:¹

Type 1 (Fig. 445). *Upon the same side as the lesion:* Cutaneous hyperesthesia of the skin to touch, bounded above by a zone of cutaneous anesthesia for all sensory qualities; above the latter area there is sometimes still another narrow zone of

¹ See Mann, *Zeit. f. Nervenkrankh.*, 1896, vol. x, and Gowers' *Handbook of Nervous Diseases*.

hyperesthesia to touch. Disturbances of sensation of the deep viscera (disturbance of the perception of passive changes of the position of the extremities and of bone sensibility).

Upon the opposite side: Cutaneous analgesia and thermanesthesia, sometimes (though more rarely than upon the same side as the lesion) bounded above by a zone of cutaneous hyperesthesia to touch. Sensation to touch intact.

Type 2 (Fig. 446). As in Type 1, except that the analgesic and thermanesthetic regions upon the side opposite to the lesion also exhibit hyperesthesia or anesthesia to touch.

Fig. 446.—Spinal hemiplegia. Lesion upon the left side of the patient. Type 2: Motor and vasomotor paralysis. Varying degree of disturbance of sensation of the deep viscera (perception of position), including the bones.

..... Cutaneous hyperesthesia to touch (also in the red shaded area).

Complete anesthesia.

— — — — — Diminished sensation to touch and abolished sensations of pain and temperature. Upon the white side there is neither motor nor vasomotor paralysis.

Type 3 (Fig. 447). As in Type 1, but, with the exception of the zones at the level of the lesion, there is no hyperesthesia to touch upon the side of the lesion; on both sides below the lesion or below the small zones of hyperalgesia there is hyperesthesia to touch (Gowers).

These different symptoms may be explained by the following assumptions: The majority of the fibers conducting the sensations of pain and temperature decussate immediately upon their entrance into the spinal cord and pass upward to the brain upon the other side of the median line. About half of the fibers conducting the sensation of touch decussate immediately and half remain upon the same side.

The fibers for the perception of passive movements of the extremities and for bone sensation run upward in the spinal cord without decussation. The uncrossed fibers probably pass upward in the posterior columns, while the crossed fibers, especially those for temperature and pain, after their decussation, run upward in the anterolateral columns. The decussation of the fibers in the latter group, if it occur at all (see above), takes place in the gray matter, since an impulse from the terminals of the collaterals in the posterior horn of one side is taken up by dendrites of the cells in

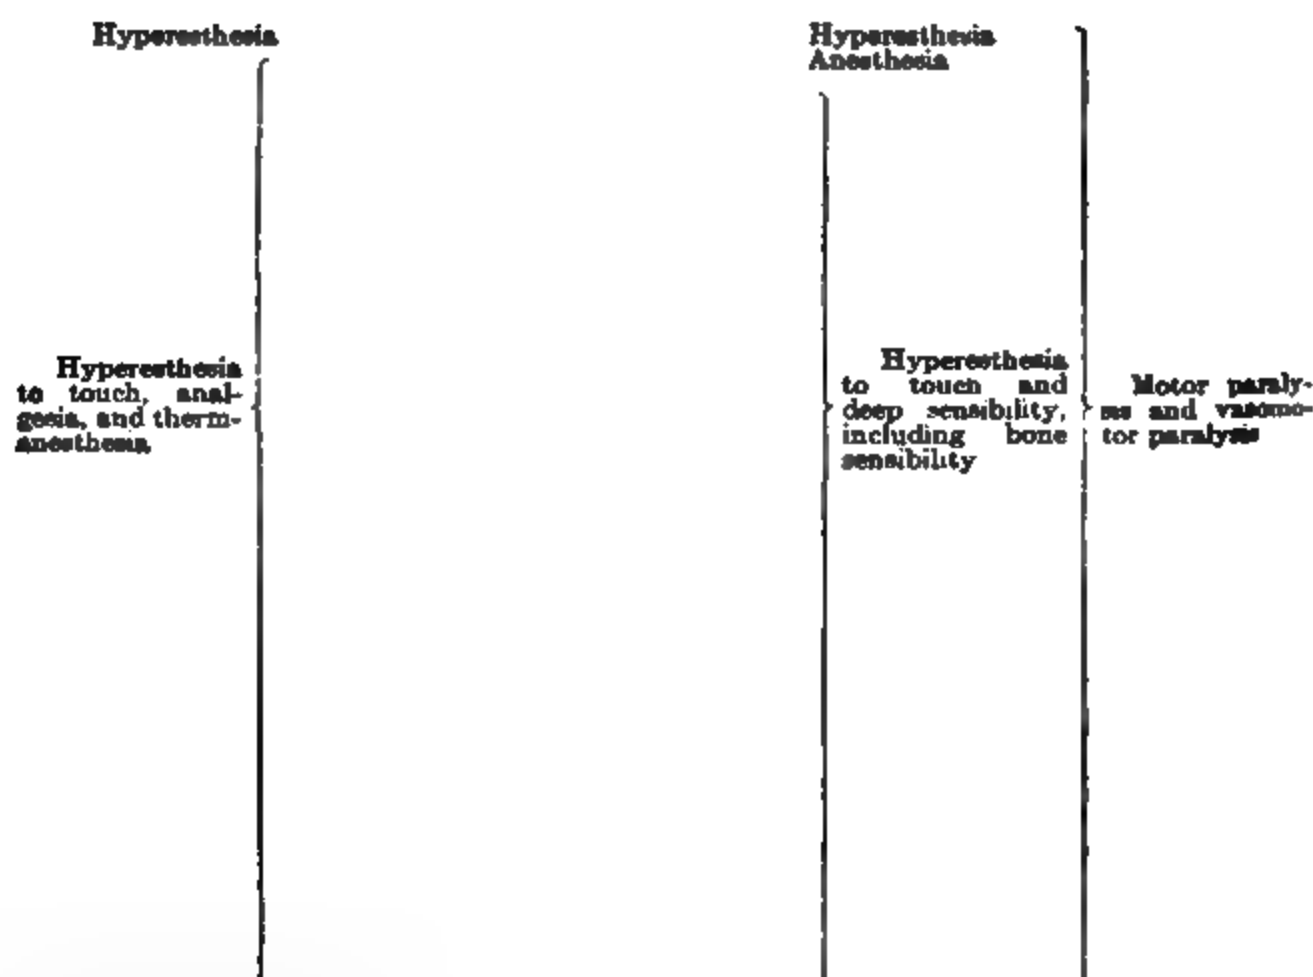

Fig. 447.—Spinal hemiplegia. Lesion upon the left side of the patient. Type 3: Motor and vasomotor paralysis. Varying degree of disturbance of sensation of the deep viscera (perception of position), including the bones.

..... Diminished sensation to touch (also in the red shaded area).

Upon the white side there is neither motor nor vasomotor paralysis.

the anterolateral column of the other side. (See Fig. 455.) It should be noted that, as the decussation never affects the entire fibers of the posterior roots, but always only their collaterals,¹ we might indicate the relation between the crossed and

¹ As is well known, every fiber of the posterior root immediately upon entering the spinal cord divides into an ascending and a descending branch, both of which give off transverse ramifications known as collaterals. These collaterals run approximately transversely in the cord, and send on the sensory impulses through their terminal arborizations.

uncrossed sensory fibers diagrammatically by representing the posterior root as consisting of a crossed and an uncrossed portion. This conception is of importance for the explanation of the hyperalgesia upon the side of the lesion. (See below.)

The most important of these assumptions are diagrammatically indicated in the accompanying illustration (Fig. 448). In order to render it more comprehensible, the sensory fibers for the perception of passive movements of the extremities and for bone sensation, as well as the motor and vasomotor fibers, have been omitted. This is more convenient because, as their course has been indicated by clinical observation, a disturbance of these tracts needs no special explanation. By the use of this diagram the differences between the sensory symptom-complexes of unilateral lesions may be readily understood.

The red lines represent the fibers for the conduction of the sensations of pain and temperature; although these sensations are not transmitted by the same fibers, they both pursue a similar course. The black lines represent the fibers for the conduction of the sensation of touch. It will be observed that each of these fibers, after its entrance into the spinal cord, divides into a crossed and a direct portion. The direct portions of the (red) fibers for the conduction of the impulses of pain and temperature are indicated by light lines, in order to give the impression that they are few in number and that they play an unimportant rôle in comparison with

Fig. 448.—Diagram of the sensory fibers to explain the phenomena of spinal hemiplegia.

the much greater number of crossed fibers. The direct and the crossed portions of the (black) fibers for the sensation of touch are, on the contrary, indicated by exactly similar lines. For the sake of clearness, no attention has been paid to the topographic arrangement of the fibers in the cross-section of the spinal cord, nor to the composition of the crossed tracts from two neurons. The shaded area represents the substance of the spinal cord which is involved by a unilateral lesion.

With the aid of this figure the sensory phenomena of Type 1 (Fig. 445) may now be explained. The perceptions of passive motion of the extremities and of bone sensation will be disturbed upon the side of the lesion because these fibers (not indicated in Fig. 448) pass upward uncrossed in the spinal cord. We can also understand that a complete transverse section of one-half of the cord will be followed by an almost complete absence of the sensations of pain and temperature upon the opposite side below the lesion (due to involvement of the heavy red lines in Fig. 448). The direct fibers for these sensations (indicated by the light red lines) are so few in number that they are unable to produce symptoms upon the same side as the lesion, and are equally powerless to prevent a marked disturbance of the sensations for pain and temperature upon the opposite side. The figure also explains why in many cases there is no diminution of the sensation to touch below the lesion, with the exception of the zone corresponding to the involved segment, since the equal division of these fibers into crossed and uncrossed tracts is evidently sufficient to

maintain the normal sensory conditions. Many theories have been advanced to explain the hyperalgesia to touch which is usually observed upon the same side and below the lesion. The author believes that this symptom can be rendered intelligible by assuming that the crossed and direct tracts for tactile sensation are mutually complementary ramifications of the sensory roots. When the direct tracts *bbb aaa* are interrupted, the crossed tracts *bbb ccc* receive a nervous impulse of double intensity, and this intensity is sufficient to cause the impulse to radiate into the dendritic network of the gray matter and excite the tract for the sensation of pain. Upon the opposite side the crossed fibers for tactile sensation are involved, and this would be followed by hyperalgesia for analogous reasons were it not that the increased intensity of tactile sensations cannot be converted into pain on account of the interruption of the tract for its transmission. The anesthetic zone observed upon the side of the lesion is explained simply by the involvement of the spinal segment by the lesion, since all of the sensory root-fibers are interrupted. The hyperalgesic zone, sometimes observed above this anesthetic zone upon the same side as the lesion, and occasionally upon the opposite side, can hardly be explained otherwise than by the supposition that the roots in the vicinity of the lesion may easily be rendered hyperirritable by inflammatory hyperemia, possibly from the meninges.

The involvement of tactile sensation in the hemianesthesia opposite to the lesion in Type 2 (Fig. 446) is explained by assuming that in these cases the crossed fibers for tactile sensation preponderate greatly over the direct. Such individual peculiarities are frequently encountered in neuropathology.

The cases of Type 3 (Fig. 447), in which, instead of hyperalgesia to touch on the same side below the lesion, we have hyperesthesia on both sides below the lesion, are explained by the supposition that the excitability of the tract for tactile sensation is so diminished that the loss of one-half of its innervation results in a decrease of sensibility, and, since the fibers run to both sides, this symptom is bilateral. Hyperalgesia is not produced below and upon the same side as the lesion on account of the diminution of the sensory irritability.

It should also be noted that, according to the condition of irritability of the sensory tracts and according to the remote effects of the unilateral lesion upon the opposite side, the symptom-complex of spinal hemiplegia is subject to still further variation.

IX. PATHOLOGIC GAITS AND POSTURES

In many diseases, and especially in nervous diseases, the way patients stand and walk shows something very characteristic, permitting a conclusion not only in regard to the type of the functional disturbance, but frequently even in regard to the anatomic nature of the disease. The following are the best-known pathologic gaits:

(a) **The Paraparetic or Paraplegic Gait.**—In paresis of both lower extremities. Both legs are brought forward slowly, dragging and trailing upon the floor.

(b) **The Hemiparetic or Hemiplegic Gait.**—In unilateral paralysis of the legs or hemiplegia. The affected leg drags after the other, or is first circumducted by a twisting movement of the pelvis and so brought forward. An explanation of this gait is to be found upon p. 1089 et seq. The predominance of the paralysis of the flexors is considered responsible for the hemiplegic disturbances of motility.

(c) **The Ataxic Gait.**—Characterized by the incoördinate ataxic nature of the movements. Sometimes the foot feels uncertainly for the ground, sometimes it is thrown outward at random or stamps, and again is lifted high from the ground, making the gait resemble that of a fowl. (See Ataxia, p. 962 et seq.)

(d) **The Spastic Gait.**—In spastic paresis of the lower extremities (spastic spinal paralysis, multiple sclerosis, etc.), the legs, being very slightly flexible, are put forward very stiffly. In putting the foot down the tendon reflexes (especially the Achilles-tendon reflex) are sometimes excited and the gait becomes characteristically jumping. The

difficulty in the spastic gait depends at one time more upon the stiffness of the knee-joints, at another more upon the knees being pressed together by the forcible action of the adductors.

(e) **The Spastic Paretic Gait.**—Combination of *a* and *c*.

(f) **The Gait of Hip-joint Disease.**—This is characterized by a rigidity of the hip-joint, so that the pelvis is largely responsible for any forward motion of the limb. Under some conditions the gait in hysteric coxalgia may be identical.

(g) **The gait in sciatica** may resemble that in hip-joint disease. The patient favors the affected leg by fixing it to the pelvis, almost as regularly as in hip-joint disease. In so-called sciatic scoliosis the vertebral column is curved while the patient is walking or standing. There are usually two characteristic curves: the lower curve is convex, the upper concave toward the affected side. The trunk is, therefore, as a rule, bent toward the healthy side (heterologous sciatic scoliosis), although the curves may be reversed (homologous sciatic scoliosis).

Attempts have been made to explain these differences in sciatic scoliosis, but it seems quite plain that no explanation is possible for them all. Albert described heterologous sciatic scoliosis, but did not venture an explanation. Lorenz assumes that this form of scoliosis is brought about simply by shifting the center of gravity to the healthy leg. Kocher explains it by an associated neuralgic affection of the sensory nerves supplying the territory of those muscles which hold the trunk straight. When the contraction of these muscles results in pain, it is no longer attempted. The spinal column, therefore, bends, its direction depending upon what nerves are thus affected.

(h) **The Choreic Gait.**—In chorea. (See Choreic Movements, p. 959.)

(i) **The Staggering Gait.**—In affections which are associated with vertigo (see Cerebellar Ataxia, p. 965, and Vertigo, p. 1092) and disturbances of equilibrium (drunkenness, cerebellar tumor, paralyzes of the eye muscles, diseases of the internal or middle ear, lead encephalopathy).

(k) **The Gait of Propulsion and Retropulsion.**—In affections with stiffness and weakness of the muscles, especially in *paralysis agitans*. This gait is peculiar in that patients once started forward or backward are not able to stop quickly, but must go on a little farther in the direction in which they are headed, because they cannot quickly enough correct the position of the center of gravity which has been shifted in the direction of their motion. Although especially frequent in *paralysis agitans*, it is not really specific, as is sometimes thought, for one often notices the same peculiarity in pedestrians who have been tired by a long tramp.

The *attitude* or mode of standing is very characteristic in many of the affections cited above. In *hip-joint disease* and in *unilateral leg paralysis* the patient supports himself entirely upon the healthy leg.

In *sciatica* the scoliotic appearances described above are very prominent. In *paralysis agitans* the position of the trunk, bent over forward, with slightly flexed knees and elbow-joints, is highly characteristic. (See the picture in Strümpell's *Lehrbuch der Pathologie*.) *Romberg's symptom* consists of more or less noticeable swaying in patients who stand with closed eyes (in severe cases even with open eyes). It occurs in anesthesia of the lower extremities, also in ataxia with or without anesthesia (especially in tabes), in affections of the cerebellum, and in

some other affections [alcoholic multiple neuritis—Z.] which lead to a staggering gait. (See above.) The sign depends upon a disturbance of the equilibrium.

X. SPECIAL POINTS IN REFERENCE TO THE EXAMINATION OF THE SPINAL NERVOUS SYSTEM

I. PLANS FOR THE EXAMINATION OF MUSCLE ATROPHIES AND PERIPHERAL MOTOR PARALYSIS¹

Upper Extremities

(For motor points, see p. 1013 et seq.)

SHOULDER-BLADE MOVEMENTS

1. *Elevation of the Shoulder-blade.*

Middle portion of the trapezius (spinal accessory).

Rhomboids (branch from fifth cervical).

Levator anguli scapulæ (second to third cervical and branch from fifth cervical).

Superior portion of the pectoralis major (anterior thoracic from fifth and sixth cervical).

2. *Depression of the Shoulder-blade.*

Pectoralis minor (anterior thoracic).

Inferior portion of the latissimus dorsi (subscapular).

Inferior portion of the pectoralis major (anterior thoracic).

3. *Adduction of the Shoulder-blade.*

Inferior portion of the trapezius (spinal accessory).

Superior portion of the latissimus dorsi (subscapular).

Rhomboids. (Branch from fifth cervical.)

4. *Abduction of the Shoulder-blade.*

Superior third of the pectoralis major (anterior thoracic).

Serratus magnus (posterior thoracic from sixth, seventh, and eighth cervical nerves).

SHOULDER-JOINT MOVEMENTS

1. *Elevation of the Upper Arm.*

(a) To the side:

Up to the horizontal: deltoid (circumflex).

Up to the vertical: deltoid and serratus magnus (posterior thoracic).

With straining, the upper part of the trapezius in addition (spinal accessory).

(b) Forward:

Anterior portion of the deltoid (circumflex).

Coracobrachialis (musculocutaneous).

Biceps (musculocutaneous).

In elevation to the vertical, the serratus magnus also aids.

(c) Backward:

Posterior portion of the deltoid (circumflex).

¹ The anatomic statements in these schemes have been collected from Scheube and Duchenne, and then compared with Gegenbauer's Anatomy (fourth edition, 1890). For the sake of simplicity, the origin of a nerve from its motor root is stated in the plan only where the nerve is mentioned for the first time. In this way it is easy enough to find the root origin of a certain nerve for a certain muscle by searching for the name of this nerve in the first place it is mentioned in the scheme. For those nerves whose origin is not stated in the scheme, the reader should consult the diagrams of the plexuses for the extremities, pp. 1158, 1159, and Kocher's plates of the spinal motor segmental innervation (Figs. 462 and 463). Further clinical experience is necessary to clear up individual points and deficiencies still under contention.

2. *Depression of the Upper Arm.*

The united adductors of the upper arm.

3. *Adduction of the Upper Arm.*

Pectoralis major (anterior thoracic from fifth and sixth cervical).

Latissimus dorsi and teres major (subscapular).

Infraspinatus (suprascapular from fifth and sixth cervical).

Teres minor (circumflex).

4. *Inward Rotation of the Upper Arm.*

Subscapularis (subscapular).

Teres major (subscapular).

5. *Outward Rotation of the Upper Arm.*

Infraspinatus (suprascapular).

Teres minor (circumflex).

ELBOW-JOINT MOVEMENTS

1. *Flexion of the Forearm.*

Biceps [flexor and supinator] (musculocutaneous).

Brachialis anticus (musculocutaneous).

Supinator longus [supinates or pronates according to the position; it is, however, chiefly a flexor in the median position] (musculospiral).

2. *Extension of the Forearm.*

Triceps (musculospiral).

3. *Supination of the Forearm.*

Supinator brevis (musculospiral).

Supinator longus (see Flexion).

4. *Pronation of the Forearm.*

Pronator quadratus (median).

Pronator teres [pronation and flexion] (median).

Supinator longus [in an extreme position of supination] (musculospiral).

WRIST MOVEMENTS

1. *Flexion of the Hand.*

Flexor carpi radialis [flexion to the radial side] (median).

Flexor carpi ulnaris [flexion to the ulnar side] (ulnar).

Palmaris longus (ulnar).

2. *Extension of the Hand.*

Extensor carpi radialis longior and brevior [extension to the radial side] (musculospiral).

Extensor carpi ulnaris [extension to the ulnar side] (musculospiral).

3. *Abduction (Radial Flexion) of the Hand.*

Flexor carpi radialis and extensor carpi radialis longior and brevior (median and musculospiral).

4. *Adduction (Ulnar Flexion) of the Hand.*

Extensor carpi ulnaris and flexor carpi ulnaris (musculospiral and ulnar).

FINGER MOVEMENTS

1. *Flexion of the Fingers.*

Flexor digitorum sublimis [flexing the second phalanx] (median).

Flexor digitorum profundus [flexing the finger from the distal phalanx] (median and ulnar. The former supplies the radial sides; the latter, the ulnar sides of the several fingers).

The interossei and lumbricales (flexing the proximal phalanx and extending the two distal phalanges). Nerve-supply principally the ulnar; in the innervation of the lumbricales, the ulnar nerve is aided by the median nerve to the extent that the latter is distributed to the two radial and a portion of the next lumbrical, while the ulnar supplies the rest.

2. *Extension of the Fingers.*

Extensor digitorum communis, extensor indicis, extensor minimi digiti [extending the proximal phalanx] (musculospiral).

Interossei and lumbricales [extending the two distal phalanges] (ulnar and median; see above).

3. *Adduction of the Fingers.*

Palmar interossei [flexing the proximal phalanx simultaneously] (ulnar).

4. *Abduction of the Fingers.*

Dorsal interossei [flexing the proximal phalanx simultaneously] (ulnar).

THUMB MOVEMENTS

1. *Flexion of the Thumb.*

Flexor longus pollicis [flexing the distal phalanx] (median).

Flexor brevis pollicis [flexing the proximal phalanx] (median).

2. *Extension of the Thumb.*

Extensor brevis pollicis (musculospiral).

Extensor longus pollicis (musculospiral).

3. *Abduction of the Thumb.*

Abductor longus pollicis (musculospiral).

Abductor brevis pollicis [more opponens than abductor] (median).

4. *Adduction of the Thumb.*

Adductor pollicis (ulnar).

5. *Opposition of the Thumb.*

Opponens pollicis (median).

Abductor brevis pollicis [more opponens than abductor] (median).

LITTLE-FINGER MOVEMENTS

1. *Flexion of the Little Finger.*

Flexor digitorum communis profundus and sublimis (median and ulnar).

Flexor brevis minimi digiti (ulnar).

2. *Extension of the Little Finger.*

Extensor minimi digiti proprius (musculospiral).

3. *Abduction of the Little Finger.*

Abductor minimi digiti (ulnar).

4. *Opposition of the Little Finger.*

Opponens minimi digiti (ulnar).

Lower Extremities

(For motor points, see p. 1013 et seq.)

HIP-JOINT MOVEMENTS

1. *Elevation of the Thigh.*

Iliopsoas [outward rotation simultaneously] (lumbar plexus).

Rectus femoris. } (crural from the first to fourth lumbar).

Sartorius. }

2. *Depression of the Thigh.*

Gluteus maximus [outward rotation simultaneously] (gluteal inferior from ischiadic plexus).

Biceps	{	(ischiadic, fourth lumbar to third sacral) [at the same time flexing the leg, but only with extension of the thigh, not in walking—Wernicke-Mann. (See p. 1088.)]
Semitendinosus		
Semimembranosus		

3. *Inward Rotation of the Thigh.*

Gluteus medius et minimus (gluteal superior from ischiadic plexus).

4. *Outward Rotation of the Thigh.*

Quadratus femoris	{	(sciatic).
Obturator internus and gemelli		

Obturator externus (obturator from second to fourth lumbar).

Pyriformis (ischiadic plexus).

Iliopsoas (lumbar plexus).

Gluteus maximus (gluteal inferior from ischiadic plexus).

5. *Adduction of the Thigh.*

Adductors [simultaneous outward rotation] (obturator).

Pectineus [simultaneous flexion] (crural and obturator).

Gracilis (obturator).

6. *Abduction of the Thigh.*

Gluteus medius et minimus (gluteal superior).

KNEE-JOINT MOVEMENTS

1. *Flexion of the Leg.*

Sartorius [simultaneous inward rotation of the flexed leg] (crural).	} Principal flexor (shortener of the leg) in walking—Wernicke-Mann. (See p. 1088.)
Gracilis [simultaneous inward rotation] (obturator).	

Semitendinosus	} [simultaneous inward rotation] (sciatic).	} Not as flexor of the leg, but as extensor of the thigh in walking (elongator of the leg—Wernicke-Mann. (See p. 1088.)
Semimembranosus		
Biceps		

Popliteus [simultaneous inward rotation] (internal popliteal from sciatic).

2. *Extension of the Leg.*

Quadriceps (anterior crural).

3. *Inward Rotation of the Leg.*

Popliteus (internal popliteal).

Sartorius (anterior crural).

Gracilis (obturator).

Semitendinosus	} (sciatic).
Semimembranosus	

4. *Outward Rotation of the Leg.*

Biceps (sciatic).

FOOT-JOINT MOVEMENTS (SCIATIC)

1. *Dorsal Flexion of the Foot.*

Tibialis anticus [elevating at the same time the inner edge of the foot] (anterior tibial nerve from sciatic).

Extensor digitorum communis longus (simultaneous abduction).

2. *Extension (Plantar Flexion) of the Foot.*

Gastrocnemii	} (internal popliteal from sciatic).
Soleus	

Peroneus longus [simultaneous abductor and elevator of the outer edge of the foot] (musculocutaneous nerve from sciatic).

3. *Adduction of the Foot.*

Tibialis posticus [simultaneous raising of the inner edge of the foot and plantar flexion of the foot] (posterior tibial nerve).

Tibialis anticus [simultaneous dorsal flexion of the foot and raising of the inner edge of the foot] (anterior tibial nerve).

4. *Abduction of the Foot.*

Peroneus longus [simultaneous plantar flexion with elevation of the outer edge of the foot] (musculocutaneous).

Peroneus brevis [pure (?) abductor with elevation of the outer edge of the foot] (musculocutaneous).

Extensor digitorum communis longus (anterior tibial).

5. *Elevation of the Inner Edge of the Foot.*

Tibialis anticus [simultaneous dorsal flexion and adduction] (anterior tibial).

Tibialis posticus [simultaneous adduction and plantar flexion] (internal popliteal).

6. *Elevation of the Outer Edge of the Foot.*

Peroneus longus and peroneus brevis (musculocutaneous).

Peroneus tertius (anterior tibial).

TOE MOVEMENTS (SCIATIC)

1. *Flexion of the Toes.*

Flexor digitorum communis longus and brevis [second and third phalanges] (tibial).

Interossei and lumbricales [first phalanx] (tibial).

2. *Extension of the Toes.*

Extensor digitorum communis longus and brevis (anterior tibial).

3. *Adduction of the Toes.*
Interossei plantares (tibial).
4. *Abduction of the Toes.*
Interossei dorsales (tibial).

GREAT-TOE MOVEMENTS (SCIATIC)

1. *Flexion of the Great Toe.*
Flexor hallucis longus [second phalanx] (tibial).
Flexor hallucis brevis [first phalanx] (tibial).
2. *Extension of the Great Toe.*
Extensor hallucis longus [second phalanx] (anterior tibial).
Extensor hallucis brevis [first phalanx] (anterior tibial).
3. *Adduction of the Great Toe.*
Adductor hallucis.
Inner belly of the flexor hallucis brevis } (tibial).
4. *Abduction of the Great Toe.*
Abductor hallucis
Outer belly of the flexor hallucis brevis } (tibial).

LITTLE-TOE MOVEMENTS (TIBIAL)

1. *Flexion of the Little Toe.*
Flexor digiti quinti (tibial).
2. *Abduction of the Little Toe.*
Abductor digiti quinti (tibial).
3. *Opposition of the Little Toe.*
Opponens digiti quinti (tibial).

2. THE PERIPHERAL DISTRIBUTION OF THE SENSORY CUTANEOUS NERVES

3. SPINAL LOCALIZATIONS

(a) Cross-section Localization of the Spinal Cord

In regard to this point the reader is referred to the text-books upon anatomy and physiology, which discuss the anatomic significance and the physiologic functions of the individual areas of the cross-section. We must be content here with inserting the two plates taken from Edinger and Obersteiner for orientation of the sensory tracts.

Anterior roots

Direct pyramidal tract

Crossed pyramidal tract

Posterior r

Type of the crossed sensory tract (principally for temperature and pain)

Fig. 455.—Cross-section of the cord (Edinger). The designation of the posterior roots not according to Edinger.

B, Burdach's column; *Ca*, anterior commissure; *Caa*, anterior cornu; *Cop*, posterior cornu; *GS*, column of Goll; *GSZ*, mixed lateral tract; *Ha*, postero-external field; *iS*, intermediate lateral tract; *KS*, direct cerebellar tract; *L*, Lissauer's marginal zone; *PyS*, lateral pyramidal tract, m, marginal zone; *PyV*, anterior pyramidal tract; *R*, substantia gelatinosa Rolandi; *Ra*, anterior roots; *SC*, Schultze's comma; *SG*, lateral boundary zone; *Sgc*, substantia gelatinosa centralis; *VG*, anterior ground bundle; *vH*, central substance behind the columns; *vm*, fasciculus subcomarginalis; *Rp*, and *W*, posterior roots.

Fig. 456.—Cross-section of the cervical cord (after Obersteiner).

(b) Segmental Localization of the Spinal Cord—Longitudinal Localization

RECENT VIEWS

Segmental Localization of Cutaneous Sensibility.—The behavior of the cutaneous sensibility in lesions of separate sensory roots, *i. e.*, of separate segments of the spinal cord, has been very minutely studied recently by Sherrington,¹ Thoburn,² and Kocher.³ Sherrington has shown experimentally that individual sensory roots, *i. e.*, segments of the dorsal cord, supply a circular girdle-shaped area of the skin upon the trunk, and that the individual segments overlap each other in both directions. Hence, the upper boundary of the disturbance of sensibility, in cross-lesions of the spinal cord, does not follow the descending direction of the ribs, but presents a girdle-shaped line perpendicular to the body axis. (See Figs. 457 to 459.) On account of the overlapping of the separate zones of sensibility, we find that in transverse lesions of the spinal cord a zone of relatively disturbed sensibility can always be distinguished above, between the boundary of the absolute loss of sensibility and the higher zone of hyperesthesia. (See p. 1126.) This zone of relatively disturbed sensibility corresponds to the area which is supplied also by the segment lying above the lesion, and which is deprived of the lower part of its double innervation. As is shown by the figure, the rules for the segmentary arrangements of disturbance of sensibility do not hold good for the extremities or the neck and head. However, if the arms be horizontally abducted, these rules still apply (Figs. 457 to 459).

In almost complete conformity with the experiments of Sherrington and with the clinical observations of Thoburn, Kocher, from minute investigation of traumatic lesions of the spinal cord, has represented in Fig. 457 the cutaneous areas corresponding to the separate spinal cord segments, *i. e.*, the sensory roots. We should supplement this figure by including the overlapping of the zones, as determined by Sherrington. In Fig. 457 the boundary between each segment and the one next below corresponds, according to Kocher, to the upper limits of the absolute disturbance of sensibility which he found in individual cases of transverse lesions of the spinal cord, *i. e.*, to the lower limits of the innervation area of the upper segment. Therefore, all these boundaries should be understood as representing the lower limits of the upper zone, *e. g.*, the boundary between the seventh and eighth dorsal zones corresponds to the lower boundary of the seventh zone, *i. e.*, to a level to which the seventh zone still sends its prolongations in lesions of the eighth segment, as a result of the double innervation; but the upper boundary of the eighth innervation area should be sought somewhat farther upward. The upper sensibility zone must, therefore, be understood to overlap the lower, like shingles on a roof, although in the figure only the uncovered parts are represented. Figs. 458 and 459 give the same representation (Seiffer and Edinger.)

The relation of the plane of the sensibility zones of the skin, *i. e.*,

of the anesthesia in lesions of the sensory roots or *focal* lesions of the cord, to the plane of the corresponding spinal cord segments, spinal root outlets, and vertebræ is of the greatest importance. Fig. 460, according to Gowers, and the following pages demonstrate plainly

Fig. 457.—The sensory innervation of the body by the spinal segments, according to Kocher. The lines represent the lower border of the upper segments.
 Red: Cervical segments.
 Brown: Dorsal
 Violet: Lumbar
 Blue: Sacral
 } The intensity of the color depends upon the level of the segment.
 C₂, D₂, L₂, S₂, etc. = Second cervical, dorsal, lumbar, sacral segment, etc.

enough that the injured spinal cord segment, the place of exit of the corresponding sensory root, or the vertebra corresponding numerically to the injured segment, and, finally, the cutaneous sensibility border do not lie in a horizontal plane, but that the cutaneous sensibility is

displaced well downward in relation to the vertebra or the exit of the nerve, and this again in relation to the segment of the cord. In the operative treatment of certain spinal cord affections, a neglect of this peculiarity has occasioned many unfortunate results. The plainest rules for use in such conditions have been recently formulated by Kocher,

Fig. 458.—Sensory innervation of the spinal segments, according to Seiffer. The lines represent in this instance the lower border of the upper segments. The illustrations of Head's zones of hyperalgesia and irradiation (Figs. 381 and 382) correspond practically to these.

agreeing with Gowers' representation (Fig. 460). They will be given later.

One reason for such caudal displacement of the limits of cutaneous sensibility, as compared with the affected segment, depends upon the fact that the spinal cord (Fig. 460) is so much shorter than the vertebral

column that the nerve-roots within the vertebral canal must take a descending course. As a result (see Fig. 461) each segment up to the fourth or fifth upper dorsal vertebra is situated at the level of the next higher vertebra. Thus, the first dorsal root arises from its segment in

Fig. 459. Sensory cutaneous innervations, according to the spinal segments, after Edinger. These lines do not represent the sensory segmental boundaries, but merely the axial directions of the segmental areas. This avoids the individual variations of the boundaries and the difficulties resulting from the overlapping of the segments.

the spinal cord behind the seventh cervical vertebra, the sixth dorsal root behind the fifth dorsal vertebra, etc. From the fourth or fifth vertebra downward the segments lie still higher in relation to the corresponding vertebra, so that the eighth dorsal segment lies behind the upper part of the seventh dorsal vertebra; the ninth segment, behind

the cartilage between the seventh and the eighth vertebra; the tenth segment, behind the lower part of the eighth; the eleventh, behind the ninth; the twelfth, behind the tenth vertebra. Thus, in the upper half of the dorsal column the difference of level between the segment and the corresponding vertebra is equal to the height of one vertebra; whereas in the lower dorsal column it approaches more and more the height of two vertebrae.

This variation of level between the segment and the corresponding vertebra naturally shows at the same time the difference in height between the segment and the exit of the corresponding roots.

Now, the upper boundaries of the absolute sensibility disturbance which correspond to a lesion of a certain nerve-root, *i. e.*, of its corresponding segment, are again lower than the point of exit of the nerve-root, because the intercostal nerves take a still further descending course to reach the skin, and because the unaffected root which lies above overlaps about one finger's breadth the area supplied by the affected root. In consequence of this in lesions of a sensory root, or in transverse lesions of the dorsal cord, the limits of sensibility (upper border of absolute anesthesia) are in the upper dorsal region, at the level of about three, in the lower dorsal from four to five, vertebrae below the points of exit of the affected roots, *i. e.*, the uppermost segments affected. Since the spinal cord segments in the upper dorsal column are situated at the distance of about one and in the lower dorsal two vertebrae above the exit of the corresponding nerve-root, the affected segment in cross-sections of the upper part of the dorsal

Fig. 460.—Longitudinal section of the spine, representing the topographic relations between the spinal segments, the outgoing roots, and vertebrae (after Gowere). It will be seen that only in the lumbar region are the spinous processes on the same level as the body of the vertebra; in the cervical region and the first two thoracic vertebrae the spinous processes correspond to the lower edge of the vertebral body; in the remainder to the upper edge of the next lower. Each cervical spinous process lies on the same level with the lowest root-fibers of the next numerically succeeding nerve. The spinal processes of the third to the tenth thoracic vertebrae correspond to the second numerically succeeding root. The eleventh process corresponds to the first and second lumbar roots, the twelfth to the third, fourth, and fifth. The first lumbar process corresponds to the second and third sacral roots; the end of the cord lies opposite the upper part of the second lumbar process.

cord is situated about four (3 + 1),

and of the lower part of the dorsal cord from six to seven, spinous processes above the upper boundaries of absolute anesthesia.

These relations are represented diagrammatically in Fig. 461.

This diagram corresponds with the rules empirically established by Kocher, viz., that in cross-lesions of the dorsal cord (*i. e.*, in lesions of its sensory roots) the upper boundaries of absolute sensibility disturbance correspond to the deepest (caudal), and to the most anterior (ventral) point (for the upper ribs) of the intercostal space in which the intercostal nerve belonging to the affected root runs. From this level the limits of sensibility are horizontal, *i. e.*, perpendicular to the vertebral column, and not oblique, like the ribs. For those roots whose inter-

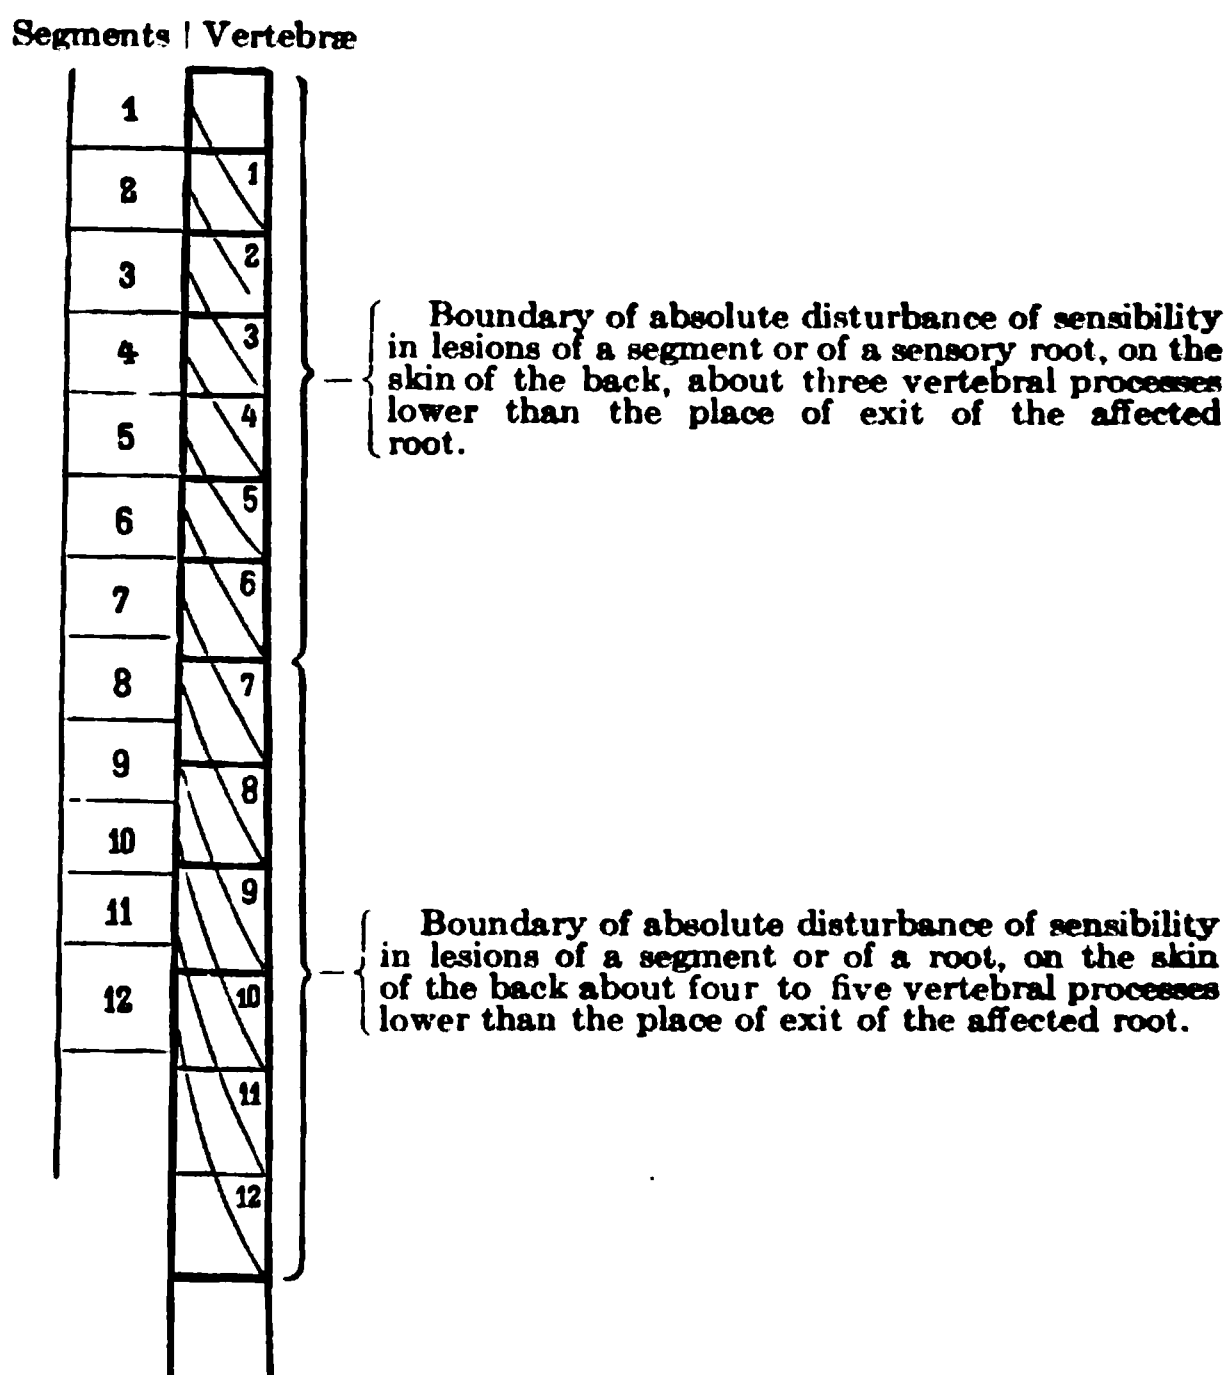

Fig. 461.—Diagram of the level of the dorsal segments in relation to the dorsal vertebrae and to the corresponding boundaries of the zones of insensibility on the back. Drawn from Kocher's rules. The oblique lines represent the emerging roots.

costal spaces do not reach the sternum, we must determine the boundaries anteriorly, corresponding to the supply of the abdominal wall, by following the intercostal nerve downward in a curve convex outward, *e. g.*, the boundaries corresponding to the twelfth intercostal nerve will reach down to the symphysis. (See Figs. 357-359, p. 1144 et seq.) In reality, Kocher's rules hold good even here, because the borders run practically horizontally backward from the deepest point of the intercostal space.

From what has been said about the difference in levels between the exit of the root and the corresponding segment, it is clear that one and the same upper boundary of anesthesia may signify lesions at different planes, depending upon whether the spinal cord or a root is involved.

myelitic softening and hemorrhages are most commonly located in the center of the cord, so that it scarcely needs to be emphasized that the rules for localization are to be applied strictly only when we are convinced that the transverse lesion affects the entire cross-section equally. This is practically very difficult. Among other aids, the condition of the reflexes may be utilized to decide the question. The more complete the involvement of the spinal cord cross-section, the more decidedly the reflexes are affected. (See p. 996 et seq.)

Segmental Localization of Motility.—Kocher has represented the motor segmental localization in the two plates Figs. 462 and 463. They are based upon his own observations and upon the well-known atlas of Flower¹ and the works of Risien Russel² and Thoburn.³ The

sacral
d V.
sacral

foot

Fig. 463.—Spinal motor nerves from lumbar and sacral plexus (Kocher).

names of the great nerve-trunks composed of the fibers from the different roots are printed in black capital letters, while the names of the individual branches are printed in italics and agree in color with the corresponding segments, i. e., the corresponding motor roots.

According to Kocher, these plates illustrate the following facts about the segmental motor innervation of the dorsal cord: First to twelfth dorsal segments supply the spinal muscles; first to eleventh

³ Loc. cit.

dorsal segments supply the intercostal muscles; seventh to twelfth dorsal segments supply the abdominal muscles; first to fourth dorsal segments furnish the sympathetic nerves to the head, neck, heart, and lungs; fifth to ninth dorsal segments furnish the sympathetic nerves to the intestinal canal and to the abdominal glands (superior splanchnic nerve); tenth to twelfth dorsal segments furnish sympathetic nerves to the testicles, bladder, and rectum (inferior splanchnic nerve, internal spermatic plexus, and inferior mesenteric plexus).

Fig. 464.—Diagram of a cerebrospinal (cutaneous) reflex to illustrate the connection between short (segmental) and long reflex tracts.

In this diagram only the cerebral reflex arc is represented completely. But the numerous collaterals (supplied with terminal twigs) show that, in addition to the shortest (segmental) circuit and to the cerebral arc, numerous spinal lateral circuits must be taken into account. This shows how incorrect it is to speak of reflex centers.

This figure explains at the same time the doctrine of reflex stasis in transverse lesions of the cord which was discussed upon p. 994. It explains why, beneath the lesion, a reflex stasis, i. e., increase, and, later, abnormality of the reflexes, and, finally, pathologic reflexes, would result from a transverse lesion (c d); whereas, if the lesion be at a b in the brain, there will be no reason for any reflex stasis, because of the countless paths of escape for the sensory irritation. Therefore, a destruction of the cerebral arc is much more apt to enfeeble the reflexes. For the sake of simplicity we have omitted any representation of the bilateral course of the tracts.

Segmental Localization of the Reflexes.—By the diagrams of the motor and sensory segmental innervation of the spinal cord (Figs. 462, 463, and 357–359), the reflexes may be localized at the appropriate segments. Their value for the local diagnosis of the level of a cross-lesion is evident. The shortest reflex tracts in the spinal cord must be contained in that portion situated between the entrance of the sensory and the motor roots which conduct the reflex in question. If one know the segment which receives the sensory irritation exciting the reflex and the segment which sends out the motor fibers inner-

vating the reflex movement, then between the two must be situated the shortest intraspinal reflex tract. This was formerly spoken of as the "reflex center." There is, of course, no question of any actual reflex center, for we have learned that there is no actual transformation of the sensory reflex impulses in one group of ganglion-cells directly to the motor limb of the so-called reflex arc. At most, such an idea can assist our conception only as a diagram does. In reality, the reflex tracts comprise numerous ganglion-cells intercalated one after the other, as well as manifold lateral connections. (See p. 990 et seq. for the modern idea of the origin of the reflexes.) The shortest path of a reflex lies between the entrance of the sensory and the exit of the motor root of the reflex arc; but this does not mean that in normal cases the reflex always proceeds only by this shortest path. On the contrary, we have already seen upon p. 993 et seq. that an upper reflex arc reaching to the brain must ordinarily be innervated at the same time, and that the shortest path can be exclusively affected only in interruptions of spinal cord conduction below the lesion, as a result of reflex stasis. Fig. 464 may recall this conception to the reader. It has been more minutely explained upon p. 993. Without any further explanation it is evident from clinical experience with hemiplegia (p. 992) that only for the tendon reflexes does the interference in the reflex arc normally occur exclusively by the shortest way (between the entrance of the sensory and the exit of the motor roots). Clinically, these shortest reflex paths are important, for, as shown in Fig. 464, in a complete cross-lesion of their segment of the spinal cord the reflexes in question must be lost, because naturally all longitudinal accompanying circuits are interrupted as well. On the contrary, we must emphasize the fact that if the shortest path is anatomically intact, the reflex in question may be either preserved or lost, depending upon whether the reflex normally proceeds by the shortest path or by a longer path, whether the latter is free or interrupted, and whether the reflexes are diminished by the indirect action of a lesion lying farther above, which causes inhibition or circulatory disturbances, or (p. 990), conversely, reflex stasis. In other words, preservation of a certain reflex shows that the segment of the spinal cord uniting its motor and sensory nerve-roots must still possess, at least, partial conductivity; whereas the loss of such a reflex suggests an interruption of the corresponding segment of the spinal cord, although it does not in any way prove such interruption with certainty.

OLDER VIEWS

In concluding this presentation of the segmental localization of the spinal cord, derived from the most recent sources, it seems necessary to include in the following pages the most essential of the older views upon this topic. The frequent contradictions which exist between individual views prove how unsettled this question still remains, and show that accurate clinical and pathologico-anatomic examinations will not only supply numerous corrections, but will extend our knowledge as well. These findings, especially where they concern the reflexes and their relation to the segments, must be critically examined for light upon the genesis of the reflexes. (See pp. 990 and 993.) Thus far the comparison of the conformity and non-conformity of individual views has been the only method of judging the accuracy of the data. In the discussion certain experiments performed upon animals are not excluded, because they are useful for the purpose of criticism. In this connection the observations made by Ferrier and Yeo upon apes by irritating the motor nerve-roots are especially valuable, particularly because many other experiments, especially the well-known researches of Horsley and Beever upon the cerebral cortex (see Figs. 425 and 426), show the most intimate analogy between the nervous

system of apes and that of man. Even the gross anatomy of the plexuses of the extremities must be taken into account, and, therefore, finds a place in the following:

CLINICAL DATA

*Localization of the Functions in the Different Spinal-cord Segments.—
(From Starr-Edinger-Bruns.¹)*

Segments.	Motor roots for—	"Reflex centers" ² for—	Sensory roots (cutaneous innervation) for—
First cervical nerve.	Small muscles of the neck, Sternocleidomastoid and trapezius.		
Second to third cervical nerves.	Sternocleidomastoid, Trapezius, Scaleri and neck muscles (complexus, splenius, longus colli).	Neck and occiput.
Fourth cervical nerve.	Complexus, Splenius, longus colli, Levator scapulæ, Diaphragm (phrenic nerve), Supra- and infraspinati, Deltoid, Biceps and coracobrachialis, Supinator longus, Rhomboidei.	Dilatation of the pupils from a sensory stimulation of the neck (fourth to seventh cervical nerve).	Neck, Upper shoulder region, Outside of the arm to the second rib.
Fifth cervical nerve.	Diaphragm (phrenic nerve), Deltoid, Biceps, brachialis anticus, Coracobrachialis, Supinator longus and brevis, Pectoralis major (pars clavicu- laris), Serratus magnus, Rhomboidei, Teres minor, Latissimus dorsi.	Scapular reflex (fifth cervical nerve to first dorsal nerve). Tendon reflexes of the muscles and tendons about the elbow-joint (fifth to sixth cervical nerve).	Posterior aspect of the shoulder and arm. Outside of the arm and forearm.
Sixth cervical nerve.	Biceps, Brachialis anticus, Pectoralis major (pars clavicu- laris), Serratus anticus major, Triceps, Extensors of the hand and fingers, Pronators.	Extensor reflexes of the arm and forearm.	Outside of the forearm.
Seventh cervical nerve.	Long head of the triceps, Extensors of the hand and finger, Flexors and pronators of the hand, Pectoralis major (pars cos- talis), Subscapularis, Latissimus dorsi, Teres major.	Flexor reflexes.	Radial area of the hand and part of the median area.

¹ Starr collected the older data from the clinical examinations of localized spinal-cord lesions, which are recorded as late as 1888.

² This expression (see p. 1152 et seq. and Fig. 464) is incorrect, and signifies here merely the shortest reflex arc, and, therefore, that segment of the cord which includes the sensory and motor roots of the reflex in question.

Localization of the Functions, etc.—(Continued.)

Segments.	Motor roots for—	"Reflex centers" for—	Sensory roots (cutaneous innervation) for—
Eighth cervical nerve.	Flexors of the hand and fingers, Small muscles of the hand.	Dilator of the pupil and smooth muscles of the orbit, with first dorsal nerve.	Median area. Ulnar area.
First dorsal nerve.	Extensors of the thumb, Small muscles of hand, Muscles of ball of thumb and little finger.	Dilator of the pupil and smooth muscles of the orbit in conjunction with eighth cervical nerve.	Ulnar area.
Second to twelfth dorsal nerve.	Back muscles, Abdominal muscles.	Abdominal reflexes in the fourth to eleventh dorsal segments; according to Dinkler, in the ninth to twelfth dorsal segments. ¹	Skin of the breast, back, abdomen, and upper gluteal region.
First lumbar nerve.	Abdominal muscles, Psoas, Sartorius.	Cremaster reflex.	Skin of the pubic region, anterior surface of the scrotum.
Second lumbar nerve.	Psoas, Sartorius, Flexors of the knee (Remak?), Quadriceps femoris.	Cremaster reflex. Patellar tendon reflex (second to fourth lumbar nerve).	Outside of the hip region.
Third lumbar nerve.	Quadriceps femoris, Psoas and pectineus, ¹ Inward rotators of the thigh, Abductors of the thigh.	Patellar tendon reflex (second to fourth lumbar nerve).	Anterior and inner side of the hip region.
Fourth lumbar nerve.	Adductors and abductors of the thigh, Tibialis anticus, Peroneus longus, Flexors of the knees (Ferrier?).	Patellar tendon reflex (second to fourth lumbar nerve). Gluteal reflex (fourth to fifth lumbar nerve).	Inner side of the hip and leg as far as the ankle. Inner side of the foot.
Fifth lumbar nerve.	External rotators of the hip, Flexors of the knees (Ferrier?), Flexors of the foot, Extensors of the toes, Peronei.	Gluteal reflex (fourth to fifth lumbar nerve).	Posterior side of the hip, of the thigh, and external part of the foot.
First to second sacral nerves.	Flexors of toes and foot, Small muscles of feet, Peronei.	Plantar reflex. Bladder and rectal center (Sarbo).	Posterior side of the thigh, outside of the leg and foot.
Third to fifth sacral nerves.	Perineal muscles.	Achilles tendon reflex. Bladder and rectal center.	Posterior side of the scrotum, Perineum, anus, sacral region.

¹ In regard to local diagnosis these data must be accepted with reserve, because it is manifest that they refer merely to the entrance and exit of centripetal and centrifugal segments of the lowest reflex arc, and because, as the abolition of the abdominal reflex on the paralyzed side in cerebral hemiplegia indicates, the abdominal reflex arc normally includes the brain.

W. Thoburn¹ has independently obtained results that are similar to but not in complete accord with those of Kocher.

BRACHIAL PLEXUS (Motor Innervation)

Cervical nerves:	
Fourth	Supra- and infraspinatus, teres minor (?).
Fifth.	Biceps, brachialis anticus, deltoid, supinator longus, supinator brevis.
Sixth.	Subscapularis, pronators, teres major, latissimus dorsi, pectoralis major, triceps, serratus major.
Seventh.	Extensors of the wrist.
Eighth.	Flexors of the wrist.
Dorsal nerves:	
First.	Small muscles of the hand.

LUMBOSACRAL PLEXUS

Lumbar nerves:	Motor Distribution.	Sensory Distribution.
First.	(?)	The iliohypogastric and ilio-inguinal nerves.
Second.	(?)	External (?) and upper region of the thigh.
Third.	Sartorius, Adductors, Flexors of the thigh.	Anterior surface of the thigh, below the region supplied by the second lumbar nerve.
Fourth.	Extensors of the knee, Abductors of the thigh.	Anterior and inner surface of the thigh.
Fifth.	Flexors of the leg.	Posterior side of the thigh, except the territory supplied by the sacral roots.
Sacral nerves:		
First.	Calf muscles, Gluteal muscles, Peroneal muscles, Dorsal flexors of the ankle-joint, Small muscles of the foot.	Narrow strip on the posterior surface of the thigh and leg, sole of foot.
Second.		
Third.		A part of the dorsum of the foot.
Fourth.	Nervi erigentes, Perineal muscles. Bladder and rectum.	Perineum, external genitals.
		Posterior surface of the thigh.

Dinkler's² observations, made in Erb's clinic, upon the localization of the abdominal reflexes, should be mentioned. He found that the abdominal reflexes have their shortest circuit in the lowest part of the dorsal cord, that the middle and lower abdominal reflexes (p. 988) belong to the tenth, eleventh, and twelfth intercostal nerves and their corresponding spinal segments, while the upper abdominal reflex is limited to the tract of the ninth and possibly, also, of the eighth dorsal nerves. This tallies with the segmental localization of the corresponding cutaneous areas. (See Fig. 457, p. 1145.) Still, these statements apply only to the shortest circuit of the reflex arc and do not exclude the longer reflex arcs reaching further up through the affected sections which have been shown at autopsy and in cerebral hemiplegia. (See foot-note, p. 1154.)

For the local diagnosis of lesions of the cervical cord the reader should consult Kraus's article (from Kahler's Clinic), *Zeit. f. klin. Med.*, 1891, vol. xviii, p. 343. In conformity with Fräulein Klumpke's experiments on animals, he found that in man the sympathetic oculopupillary fibers, whose paralysis causes myosis and retraction of the globe with sympathetic ptosis (Paralysis of Müller's Smooth Orbital Muscle, see p. 1046), leave the spinal cord with the motor root of the first dorsal nerve. These are the fibers which connect the principal trunk of the sympathetic with the so-called ciliospinal center of the spinal cord. The latter was localized by Budge between the sixth cervical and the second dorsal segments. Kraus's statements coincide with

EXPERIMENTAL DATA

Ferrier and Yeo,² in irritation experiments upon apes, obtained the following results in reference to the assignment of individual muscles to the motor-nerve roots:

MOTOR ROOTS OF THE BRACHIAL PLEXUS (after Ferrier and Yeo).

Fourth Cervical Nerve.—Deltoid, rhomboids, supra- and infraspinatus, teres minor, brachialis anticus, supinator longus, extensors of the hand and fingers, diaphragm.

Fifth Cervical Nerve.—Deltoid (clavicular portion), biceps, brachialis anticus, serratus anticus major, supinator longus, extensors of the hands and fingers.

Sixth Cervical Nerve.—Latissimus dorsi, pectoralis major, serratus magnus, pronators, flexors of the wrist (?), triceps.

Seventh Cervical Nerve.—Teres major, latissimus dorsi, subscapularis, pectoralis major, flexors of the hand and fingers (median), triceps.

Eighth Cervical Nerve.—Long flexors, flexor carpi ulnaris, small muscles of hand, extensors of the hand and fingers, long head of the triceps, pectoralis major (?).

First Dorsal Nerve.—Small muscles of the hand.

MOTOR ROOTS OF THE LUMBOSACRAL PLEXUS (after Ferrier and Yeo).

Third Lumbar Nerve.—Psoas, sartorius, adductors, extensor cruris.

Fourth Lumbar Nerve.—Extensors of the thigh, extensor cruris, peroneus longus, adductors.

Fifth Lumbar Nerve.—Flexors and extensors of the toes, tibial muscles, calf muscles, peroneal muscles, external rotators of the thigh, flexors of the leg (biceps, semitendinosus, etc.).

First Sacral Nerve.—Calf muscles, flexors of the leg, flexor hallucis longus, small muscles of the foot.

Second Sacral Nerve.—Small muscles of the foot.

Dastre and Morat found, in experimenting upon animals, that most of the vaso-motor and sweat-secretory fibers for the face first leave the cord with the second to sixth dorsal nerves.

Additional experimental results worth mentioning are those obtained by Nawrocki and Skabitschewsky upon the origin of the motor and sensory fibers for the bladder of the cat. They found that the motor nerves of the bladder leave the spinal cord by two paths—an upper and a lower. The upper leads to the vesical plexus from the fourth and fifth anterior lumbar roots; the lower from the second and third anterior sacral roots. The sensory fibers are partly sympathetic, partly cerebrospinal, in origin; the former are contained exclusively in the hypogastric nerve, the latter in the four upper posterior sacral roots. (See also L. B. Müller's data on p. 1167 et seq.)

Rossolimo found in dogs that the center for the *anal reflex* (p. 988) was situated in the region of the third and fourth sacral nerves.

PURELY ANATOMIC DATA

Herringham³ obtained the following results in regard to motor innervation from purely anatomic researches upon the course of the individual motor nerve-roots through the brachial plexus:

Fifth Cervical Root.—Biceps, brachialis anticus, subscapularis, deltoid.

Sixth Cervical Root.—Pectoralis major, biceps, brachialis anticus, pronator teres, flexor carpi radialis, thenar muscles, subscapularis, teres major, deltoid, supinator longus and brevis, extensor carpi radialis, longior and brevior.

Seventh Cervical Root.—Pectoralis major and minor, coracobrachialis, flexor sublimis, latissimus dorsi, triceps, radialis externus, longus and brevis.

¹ Zeit. f. klin. Med., 1899, vol. xxxvii.

² Brain, 1882, vol. iv, p. 226.

³ Proc. Royal Soc., 1886, No. 243, p. 225.

Eighth Cervical Root.—Pectoralis major and minor, flexor sublimis, latissimus dorsi, triceps.

First Dorsal Root.—Pectoralis major and minor.

At all events, we have anatomic examinations to thank for the knowledge that the *phrenic nerve*, to a large extent, derives its fibers from the *fourth motor*

Fig. 465.—Plexus brachialis: IV, V, VI, VII, VIII, I, Anterior branches of the five lowest cervical nerves and of the first dorsal nerve. Of the branches extending anteriorly, only the subclavius nerve is represented (after Gegenbaur).

cervical root, and sometimes a part from the third and fifth; the *occipitalis magnus* derives its fibers from the second, the *occipitalis minor* from the first, second, and third, and the *auricularis magnus* from the third and fourth *sensory* cervical roots.

The annexed figures (465 and 466) and Gegenbaur's *Lehrbuch der Anatomie* may be consulted for a general idea of the origin of the plexuses for the extremities, and their subdivisions into the peripheral nerves.

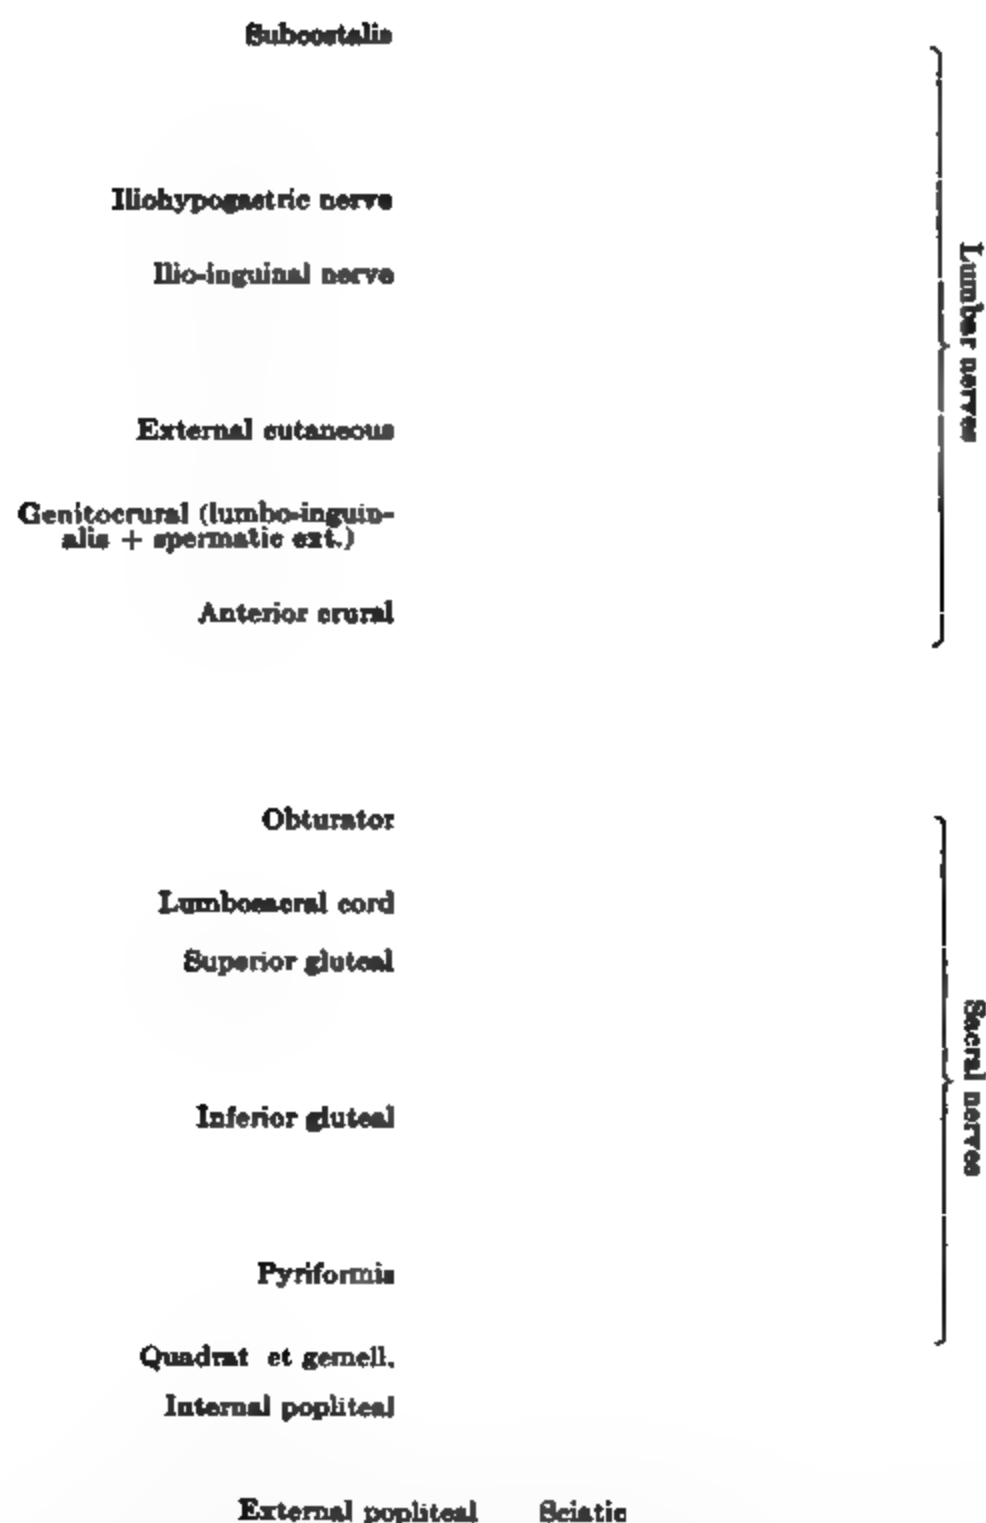

Fig. 466.—Lumbosacral plexus: *ps*, Branches to the psoas muscle; *il*, branches to the iliac muscle (after Gegenbaur). In the sacral division, the sciatic plexus which forms the sciatic nerve is split up into its component parts (according to Paterson).

(c) Topography of the Lumbosacral Cord, of the Conus Terminalis, and of the Cauda Equina

In order to make a differential diagnosis and determine the definite localization of affections of the cauda equina, of the lumbar and sacral cord, and of the conus terminalis, it is very essential to possess an exact knowledge of the topographic relations of this region and especially of the situation of the points of origin of the lumbar and sacral nerves from the cord, as compared with the vertebrae or the points of exit of the nerve-roots from the spinal-cord canal. The following plates will serve for orientation.

The limits of the conus terminalis have not yet been very sharply defined. Raymond puts its upper borders sufficiently high to include the centers or the medullary origins of the last three sacral nerves. Such delimitation conforms both with the requirements of descriptive anatomy, i. e., with the boundaries of

the actual wedge-shaped terminal portion of the spinal cord, and with those of clinical experience, *i. e.*, the clinical picture of a lesion of the second lumbar vertebra.¹ In lesions of the *conus terminalis*, both motility and sensibility of the lower extremities are practically intact, but the functions of the bladder and rectum are disturbed, and there is an anesthesia of the perineum, the inferior gluteal region, and of a zone upon the back of the thigh, which is supplied by the posterior femoral cutaneous nerve. This does not entirely coincide with the topography of sensibility disturbance pictured upon p. 1144. A lesion of the lower part of the *cauda equina* will, of course, produce a similar clinical picture.

Fig. 468 shows, according to Schultze, that the clinical picture of still higher lesions of the lowest portion of the cord may be simulated by lesions of the *cauda*

Fig. 467 —The lower end of the vertebral column and its topographic relation to the lumbar and sacral cord, and to the origins and exits of the lumbar and sacral nerves. The cross-shaded portion represents the *conus terminalis*, according to Raymond's definition (see the text), to which is attached the *filum terminale*. Between it and the wall of the vertebral canal (the part in white) the *cauda equina* passes. The upper horizontal lines indicate the heights at which the nerve-roots spring from the spinal cord, and the lower horizontal lines connected with the upper ones by means of vertical lines indicate the exits of the corresponding roots from the vertebral column. The vertical lines thus represent the lengths of the separate roots of the *cauda equina* (after Raymond²).

equina. It is quite plain from the drawing that the lesion A, at the most inferior portion of the spinal cord, and the lesion B, at the height of the third lumbar vertebra, which injures the *cauda equina*, will produce the same motor and sensory disturbances of the sciatic region and will not involve the crural and obturator region (second to fourth). A hyperesthesia of the crural region, or a very slight

¹ A Schiff (from Schrötter's Clinic), A Case of Hematomyelia of the *Conus Terminalis*, *Zeit. f. klin. Med.*, 1896, vol. xxx, p. 87.

4. THE VESICAL AND RECTAL FUNCTIONS

The Mechanism of the Vesical and Rectal Functions under Physiologic and Pathologic Conditions

It is difficult to understand the vesical and rectal disturbances occurring in diseases of the nervous system, since our knowledge of the physiologic evacuation of the bladder and rectum is still quite incomplete and contains much that is hypothetic. In studying this subject we are confronted by a special difficulty, because the old teaching that the central mechanism for the vesical and rectal functions is situated in the spinal cord has been overthrown. The prevailing opinion at present, based upon the work of Goltz, Freusberg, Ewald,¹ and particularly upon the recent work of L. R. Müller,² inclines to the view that the central mechanism for the vesical and rectal functions is situated in the sympathetic system. Since this question has not been absolutely decided, but requires further investigation (which may show that both conceptions possibly contain a portion of the truth), the author feels bound to give, first, the old, and then the newer, teaching, and to conclude with a few remarks as to the possibility of combining the two theories. (See p. 1169.)

I. The Old Conception of the Vesical and Rectal Functions, in which the Central Mechanism was Supposed to be in the Spinal Cord.—*The Physiologic Mechanism of the Vesical Functions.*—The following diagram of the innervation of the bladder (Fig. 469) should be of assistance in comprehending the clinical features of the question.

Bl represents the bladder. The detrusor muscle is represented by a thick line, the mucous membrane by a dotted line. The voluntary sphincter, which is composed of the different voluntary muscles surrounding the urethra³ (Krause's musculus urethralis) is represented by two circular cross-sections at both sides of the bladder orifice, *b'*.

The points *a*, *b*, *c*, represent the so-called bladder centers, as they have been thus far usually conceived.

a corresponds to a sensory cell, or, better expressed, a cell in connection with the sensory terminal arborizations of the tract *a* to *a'*; *b* represents a motor cell for the sphincter; *c* represents a motor cell for the detrusor. *a* should be conceived to be connected with the mucous membrane by means of the sensory tract *a* to *a'*; *b* with the sphincter by the motor tract *b* to *b'*; and *c* with the detrusor by the motor tract *c* to *c'*.

The normal bladder reflex takes place in this way: When the bladder fills, the mucous membrane stimulates the tract *a'* to *a*. From *a* the stimulation proceeds to the sphincter center *b*, and from there, in the form of a tonic innervation, to the sphincter, *b'*, which then shuts the bladder more powerfully. When the filling increases still further, until a certain degree of distention is reached, a more intense stimulation *a'* to *a* proceeds from *a* even to *c*, and finally causes a contraction of the detrusor. The bladder will then be emptied. The normal bladder reflex, therefore, consists of two acts: the closing reflex and the emptying reflex. We have included in our diagram the longitudinal

¹ Pflüger's Arch., vols. viii, ix, lxiii.

² Zeit. f. Nervenheilk., vol. xxi, parts 1 and 2.

³ The so-called "smooth sphincter" probably plays no important physiologic function.

tracts, which have an influence upon emptying the bladder; they have been demonstrated both physiologically and clinically, ascending and descending within the spinal cord. They are:

1. The tract a to A , a sensory tract leading to the brain, which informs us how full the bladder is.

2. The tract $B b b'$, subserving the voluntary innervation of the sphincter. As we cannot voluntarily innervate the detrusor, it probably does not possess an analogous tract.

Fig. 469.—Scheme for the physiologic mechanism of the bladder functions.

3. The tract β to b , which inhibits the tonus of the sphincter. Since there is no voluntary detrusor tract, βb presides over the voluntary emptying of the bladder.

4. The tract D to d , inserted upon the left of the annexed diagram, comes from the brain and innervates the abdominal muscles concerned in straining movements, therefore, assisting in forced voluntary emptying.

Voluntary emptying of the bladder takes place normally by means of these longitudinal tracts. For, after we have become cognizant of

the bladder distention and of the necessity for emptying it by means of the tract a' to a , we voluntarily relax the sphincter by an innervation along $B b b'$. This gives free scope to the reflex innervation of the detrusor by the path $a' a c c'$. Under some circumstances, when urination is urgent, abdominal pressure is called in to assist by way of the tract $D d$.

It should, of course, be understood that the longitudinal tracts, both sensory and motor, are bilateral,¹ and that their radiations on each side are in connection with both hemispheres of the brain. One hemisphere would, therefore, be sufficient to care for the voluntary function (both sensory and motor) of the bladder (as in the case of the eye muscles, p. 1041, Fig. 403).

A Brief Consideration of the Behavior of the Bladder Function in Various Lesions of the Nervous System

Functions of the Bladder in Cerebral Affections.—Since ordinarily only one hemisphere is involved in diseases of the brain and, therefore, not all the fibers passing from the brain to the spinal cord are injured, and since the long tracts to the bladder are bilateral, lesions of the long tracts usually do not produce disturbances of the bladder in cerebral diseases, except from affections of the medulla and the pons. In the latter case, on account of the close proximity of the bilateral tracts, results are like those produced by lesions of the spinal cord. (See below.)

Bilateral cerebral lesions, on the contrary, may lead to disturbances in the bladder function, especially if they are diffused. This is because the bladder tracts are not arranged in the brain compactly in a bundle, but seem to spread out diffusely. These disturbances are ordinarily associated with disturbances of consciousness. An unconscious person allows his urine to escape because he has no will-power and no sensation. He is obliged to trust everything to the reflexes. The bladder reflex may be entirely unaffected, so that from time to time the bladder is emptied quite normally, even though unconsciously and involuntarily. Quite severe conditions of unconsciousness may lead to retention of the urine, with an eventual overflow of the overfilled bladder (paradoxical incontinence). These cases are most readily explained, as in spinal-cord affections (see below), by assuming loss of inhibition of the sphincter reflexes. The bladder may be similarly affected by brain injury in any serious illness, such as typhoid fever, etc.

Functions of the Bladder in Diseases of the Spinal Cord.—The following possibilities are conceivable:

1. The bladder center itself is injured. Both the sphincter and the detrusor reflexes are lost. The bladder behaves like a mere bag. The urine trickles continually, of course, only after the bladder has been more or less distended, as a certain pressure of the urine is required to open the urethra. This is a condition of incontinence, with a more or less marked retention (incontinence of the distended bladder, *incontinentia paradoxa*). Sounding by means of a catheter proves the existence of an actual bladder paralysis. The opposition of the sphincter is lost, and the contents of the bladder can be quite easily expressed by manual pressure upon the lower abdominal region.

¹ For the sake of simplicity our diagram shows only a unilateral arrangement of the tracts.

2. The bladder center is intact, the lesion is located above the center, and only the long tracts which lead to the brain are injured. The influence of volition upon emptying the bladder will be more or less completely lost. If the injury to the long tracts be complete (and this is the usual effect of any pronounced focal lesion of the spinal cord, everything being so crowded together in a narrow cross-section), the patient will not be conscious of any distention of the bladder, nor possess any voluntary influence over it. One would naturally suppose that at least the reflex activity of the bladder would be normal; but this is only rarely true. To be sure, in exceptional cases of a cross-lesion of the spinal cord above the so-called bladder center, patients (especially children) will empty the full bladder, from time to time, in a perfectly normal fashion (pure enuresis), but entirely involuntarily. Perhaps this type of disturbance occurs only in the less complete interruptions of conduction. But much oftener these patients suffer from urinary retention; the bladder becomes more and more distended; the sphincter finally gives way; and the urine trickles out. Such a condition of incontinence with an overfilled bladder is called *paradoxical incontinence*. The distinctive appearance of decided retention, which is always much more pronounced in these cases than in those under the first head, is to be explained by assuming that in extensive cross-lesions of the spinal cord above the bladder center, the tract inhibiting the sphincter reflex (β b, Fig. 469, p. 1163) is injured as well as the other long tracts. Analogous to the increase of tendon reflexes usually accompanying these cases, the tonus of the sphincter is naturally accentuated enough to overcome the power of the detrusor, and retention consequently ensues.

3. The lesion is situated below the bladder center. Since both sensory and motor fibers for the bladder run down from the bladder center within the spinal cord for a short distance before they pass out, such a focal lesion will partially interrupt the reflex arc of the bladder. The effect must, therefore, be similar to that of a lesion of the bladder center itself. (See 1, p. 1164.) As we do not know just where the motor and sensory bladder nerves leave the spinal cord, it is conceivable that, below this spot, an area in the spinal cord might exist injury of which would not affect the bladder function because the bladder nerves would already have left the spinal cord. Clinical experience, however, points to the improbability of such a supposition, and the diagram (Fig. 463, p. 1150), representing a deep exit of the motor nerves of the bladder, should, therefore, be considered as accurate. The statements of physiologists in regard to position of the "bladder center" are so contradictory, and the physiologic methods of examining this question are so ambiguous, that we must provisionally depend upon clinical experience. The latter suggests that the human bladder innervation is represented even at the end of the spinal cord.

The Bladder Functions in Peripheral Affections of the Bladder Nerves.

—The function of the bladder is rarely disturbed in these affections, possibly because the relatively short course of these nerves renders their power of conductivity especially favorable. Still it should be remembered, in regard to the differential diagnosis between poliomyelitis and polyneuritis that bladder disturbances may appear in the latter. In any given case the type of disturbance can be easily explained by consulting the diagrams.

Another Representation of the Bladder Functions.—The preceding diagram should be regarded as wholly theoretic. It depends upon the unproved assumption of a circumscribed bladder function in the spinal cord. (See p. 1151 et seq. for arguments against such a theory.) This assumption is based upon the fact that complete paralysis of the bladder (p. 1164, No. 1) has been proved, both experimentally and clinically, to occur with disturbances in the territory of the lowest part of the spinal cord. This fact may, however, be perfectly explained in another way by assuming that the importance of the lumbar and sacral cord in controlling bladder functions depends upon the compact arrangement of the sensory and motor fibers of the bladder at their exit there from the spinal cord; whereas, higher up, they perhaps spread out diffusely through a large portion of the longitudinal and cross-sections of the cord. Although, without doubt, the shortest reflex arc (i. e., the shortest connection between the sensory and motor bladder nerves) is localized in the

Fig. 470.—Scheme of bladder functions with superimposed reflex arcs.

lowest portion of the spinal cord, this does not necessarily prevent the circuit of the reflex arc from reaching high up into the spinal cord (perhaps even to the brain).¹ The pathologic affections of the bladder functions can be explained as well, and perhaps more readily, by Fig. 470 than by Fig. 469, provided that we make such an assumption and consider the mechanism of the bladder functions analogous to the mechanism of the cutaneous reflexes. (See p. 993 and Fig. 464, p. 1151.) In Fig. 470 we need to assume only that the reflex arcs for the detrusor reach high up in the spinal cord, or even as high as the brain; whereas, the sphincter reflex takes place principally by shorter tracts (in the lumbar enlargement). This conception readily explains the occurrence of retention of urine (paradoxical incontinence) in all complete cross-lesions situated above the lumbar enlargement, for the detrusor reflex would then be injured more than the sphincter reflex. This conception does not need to assume a definite center to explain the fact that severer bladder disturbances result from lesions of the lumbar enlargement, for, according to this assumption, a lesion here affects the entire centripetal and centrifugal bladder innervation. Again, it explains most readily the variations of the less typical bladder affections in which the bladder fibers for the different functions must be assumed to be variously affected; for, when we represent the reflex apparatus of the bladder (as in Fig. 470) distributed through the entire spinal cord and even to a part of the brain, it becomes perfectly natural to conceive that the bladder mechanism can be injured in manifold ways, as is especially the case in system diseases like tabes.

So far as the voluntary control of the bladder is concerned, Fig. 470 should be regarded in the same way as Fig. 469, and should be completed by adding the voluntary tracts for the closure and relaxation of the sphincter, as well as those innervating the muscles concerned in abdominal straining.

We might add that the principle of the bladder innervation is not influenced by assuming in both Figs. 469 and 470 that parts of the reflex arc run in sympathetic tracts.

Mechanism of Emptying the Rectum under Physiologic and Pathologic Conditions.—The emptying of the rectum is accomplished in the same way as the emptying of the bladder. With the proper changes, what has been said about the latter applies to the rectum. The old conception of a rectal center localized in the lumbar enlargement of the spinal cord (see Fig. 469) becomes less probable when we assume that the

¹ The theory that the reflex tracts of the bladder reach up into the brain agrees with the fact that the bladder functions are not necessarily destroyed by focal lesions of the brain, as the tracts in question must be situated bilaterally in the brain, while most cerebral lesions only affect one side. Moreover, the exceptional cases where cerebral lesions do affect the bladder functions are most easily explained by this assumption.

reflex arcs of the rectum (like those of the bladder in Fig. 470) run far up into the spinal cord, and perhaps even into the brain. Either theory will explain (as with the bladder) the fact that lesions of the lumbar and sacral cord produce an actual paralysis of the rectum; whereas lesions higher up cause, for the most part, a decided retention of feces. Clinically, however, the picture of fecal accumulation caused by paralysis of the detrusor reflex or by increase of the sphincter tonus can be altered if the peristalsis of the upper part of the gut, which is not under the direct control of the spinal cord, be sufficient to expel the fecal masses from the rectum in spite of the retention. On the other hand, the picture of sphincter paralysis in the rectum may be modified and much less noticeable if the fecal masses be hard enough to remain in the rectum, despite a weak or absent closure of the sphincter.

II. The New Theory of Sympathetic Vesical, Rectal, and Ejaculatory Centers (*Goltz, Freusberg, Ewald, L. R. Müller*).—The theory of the spinal localization of the vesical and rectal centers has long since been shaken by the experiments of Goltz, Freusberg, and Ewald.¹ These writers demonstrated that in dogs, after the removal of the lowermost portion of the spinal cord, which presumably contained the vesical and rectal centers, the primarily disturbed vesical and rectal functions became normal after a time. The theory of the spinal localization of the centers for the vesical, rectal, and ejaculatory functions had become so deeply rooted during the preceding fifty years, however, that it continued to dominate physiologic, as well as clinical, teaching. Since L. R. Müller's recent important experiments² have completely confirmed those of Goltz's school and shown that the centers for the vesical and rectal functions and for the male sexual act are situated outside of the spinal cord in the sympathetic system, we must determine to what extent our clinical ideas should be revised.

The experimental results attained by Müller are essentially as follows: If the spinal cord of the dog be divided above the sacral segments, or if the sacral segments be extirpated, the result is practically the same. At first there is retention of the urine and of the feces. The bladder may be mechanically evacuated by pressure, and if this be not done regularly, the bladder overflows (paradoxical incontinence). After a time, however, this urinary and fecal retention disappears and is replaced by periodic evacuations differing from the normal only in that they are involuntary. Since this reestablishment of periodic evacuations occurs even after complete extirpation of the lumbar and sacral cord, the central mechanism for these functions evidently must be situated outside of the spinal cord in the sympathetic system. Experiments in reference to the localization of the sexual functions in male dogs led to similar results. After the extirpation of the sacral and of a great portion of the lumbar cord, the dogs are capable not only of erection, but also of ejaculation. The center for this function must, consequently, also lie outside of the spinal cord. In these experiments, however, the lesion of the spinal cord necessarily produces certain changes of the functions. Extirpation of the lowermost portion of the spinal cord, or simply transverse section, is followed by a complete loss of the influence of the will upon the evacuation of the bladder and rectum, and such evacuation becomes purely automatic, as may easily be recognized from the behavior of the animal. The animals are, of course, anesthetic for the process of evacuation. Immediately after extirpation of the sacral cord the anus gapes from paralysis of the striated sphincter, but it gradually becomes closed, evidently as a result of the vicarious action of the involuntary musculature of the internal sphincter. The striated sphincter, however, remains paralyzed, and the anal reflex (p. 988) is permanently destroyed. If the spinal cord be simply divided above the sacral segment, the tonus of the sphincter and the anal reflex are maintained; in fact, both may even be accentuated. The voluntary perineal muscles which assist in the voluntary closure of the bladder are possibly affected in the same manner as the external sphincter of the anus, although Müller makes no definite statements in this connection. They are paralyzed by destruction of the sacral cord, but the closure of the bladder is effected vicariously by the involuntary sphincter. The experimental results seem to indicate that reflex erection is associated with the maintenance of the lowermost portion of the sacral cord, but that psychic erection is dependent upon the maintenance of the lower dorsal cord. The lower sacral cord consequently seems to receive the sensory fibers from the penis, and to give rise to the genital reflex, while the centrifugal fibers from the brain to the sexual centers evidently leave the spinal cord in the lowermost dorsal segment. Semen may be discharged even after the destruction of the lowermost portion of the spinal

¹ Pflüger's Arch., vol. viii, ix, and lxiii.

² Zeit. f. Nervenheilk., vol. xxi, parts 1 and 2.

cord, but a vigorous reflex ejaculation is dependent upon its integrity, i. e., upon the innervation of the voluntary muscles (bulbocavernosus, etc.).

From these experimental data it is easy to assume: (1) That the actual centers for the evacuation of the bladder and rectum, as well as those for erection and ejaculation, are situated outside of the spinal cord in the sympathetic system; (2) that motor fibers reach this sympathetic apparatus through the spinal cord by means of the rami communicantes, from the lumbar and sacral segments; and (3) that the motor fibers for the striated muscles of the pelvic floor, which effect the voluntary closure of the bladder and rectum, and aid during ejaculation, also the motor fibers to the muscles concerned in abdominal straining, arise directly from the spinal cord, and have nothing to do with the sympathetic. The sensory impulses for the reflex innervation of these muscles and to the brain are necessarily conducted by the spinal cord. According to this conception, the only part played by the spinal cord in the vesical and rectal functions and the genital reflex is the conduction of sensory impulses to the brain and of voluntary cerebral impulses for the innervation and

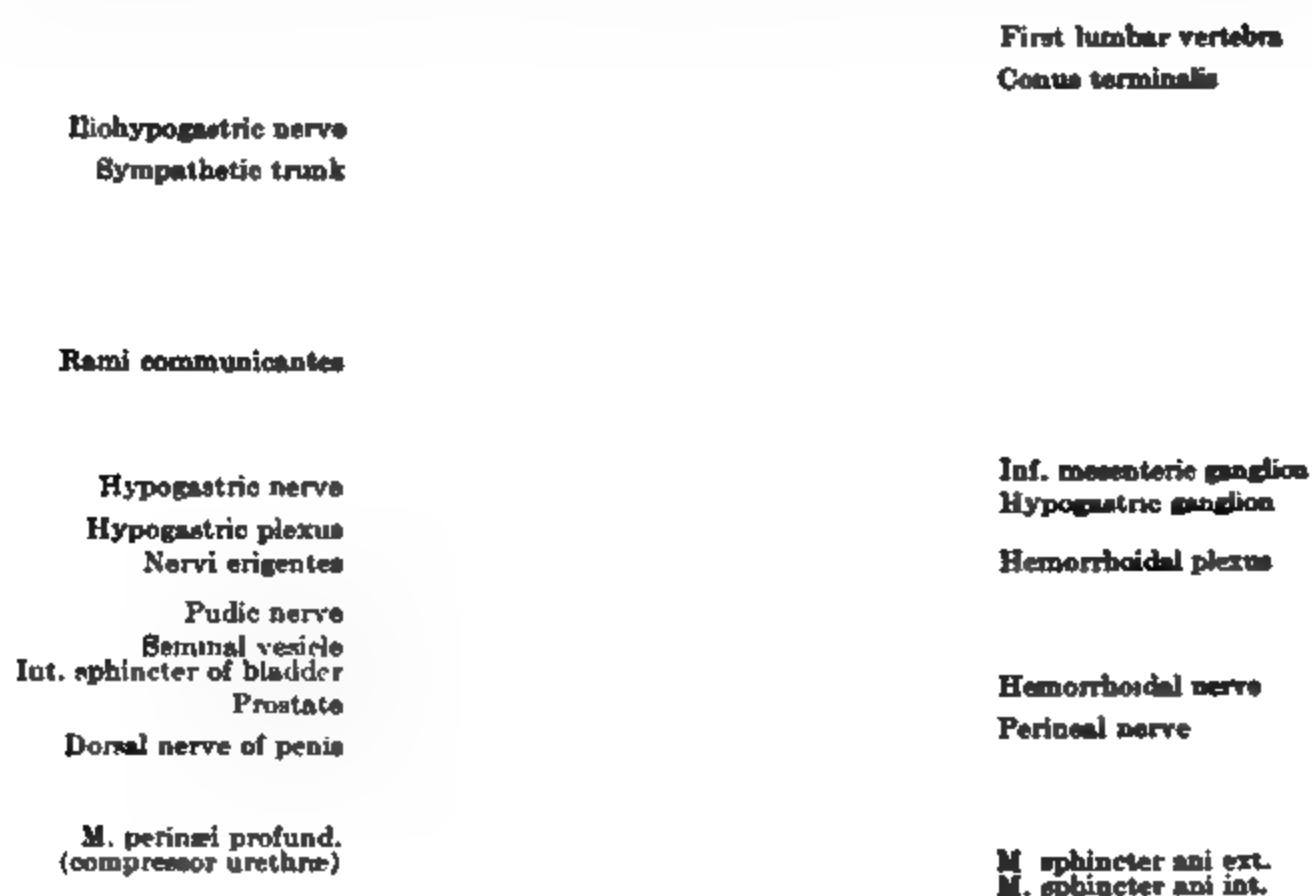

Fig. 471.—Diagram of the rectal and vesical innervation (according to Müller).

relaxation of the striated vesical and rectal sphincters, for the innervation of the muscles concerned in abdominal straining, and for the reflex influence upon these voluntary muscles. The actual bladder and rectal reflexes may be accomplished autonomously by the sympathetic, without the aid of the spinal cord.

Supported by his own investigations, as well as by those of Rehfisch,¹ Müller completely repudiates the old theory of the spinal centers for the bladder, rectum, and ejaculation, and constructs the diagram shown in Fig. 471 for the explanation of the clinical symptoms in patients with affections of the spinal cord, in which only the sympathetic plexus is to be regarded as a central mechanism.

According to this new theory, the clinical symptoms in the human subject are easily explained if we assume, with Müller, that in all destructive lesions of the spinal cord, whether they involve the sacral, the lumbar, or higher regions, the primary disturbance is always urinary and fecal retention, followed by paradoxical incontinence, that typical periodic evacuations are always established later, and

¹ Virchow's Archiv, vol. cxi.

that permanent disturbances in affections of the spinal cord, like the initial retention and parodoxic incontinence, are due simply to the absence of sensation as well as of the voluntary components of evacuation. Further investigations are necessary, however, to determine whether these suppositions are really in accord with clinical observations. The peculiar vesical disturbances in *tabes dorsalis* are certainly easy of explanation by Müller's theory, even without assuming, as does Müller, that in these cases the *tabes* is localized in the sympathetic. Also according to Müller's theory the sensory disturbances in *tabes* are sufficient to explain both the retention and the slight phenomena of incontinence in these patients, since the regulating influence of the spinal cord and brain is more or less impaired as a result of the disturbed vesical sensibility. The sexual disturbances in patients with affections of the spinal cord may also be easily explained by Müller's diagram if we remember that the lesion hinders the transmission of the psychic excitations from the lower dorsal cord to the sympathetic sexual center, and that variations of the reflex irritability of the lowermost portions of the cord in spinal lesions may increase or diminish the reflex components of erection or ejaculation. (See above.) The fact that patients with destruction of the sacral cord and complete motor and sensory paralysis of the lower half of the body are still capable of procreation (examples of which are given by Müller) is best explained by the new theory.

It must be said that Müller's theory contains much that is plausible in reference to the non-striated musculature of the bladder and rectum, the spinal innervation of which, according to the old theory, always seemed rather dubious. His experiments also seem to be quite convincing, but the author, nevertheless, believes that they are not entirely free from objection. For instance, these experiments, as well as those of Goltz and Ewald, have not certainly demonstrated that the vesical and rectal functions are carried on with the same vigor and precision after the destruction of the spinal cord as they were before, that the strength of the involuntary sphincters and detrusors does not also suffer, and that the degree of distention of the bladder and rectum prior to evacuation is the same without the influence of the spinal cord as it is with it. If we assume, according to the old theory (p. 1166 et seq.), that the reflex mechanism of the bladder and of the rectum consists of a number of superimposed reflex arcs, it becomes quite plausible to conclude that the lowermost of these is situated in the sympathetic, and that it is associated with spinal, and even cerebral, reflex arcs in such a manner that in case of necessity the sympathetic may carry on these functions, but that the finer and more vigorous functions are possible only with the coöperation of the spinal cord and brain. It is possibly a verbal quibble whether we regard the functions of the sympathetic, of the cord, and the brain as occurring in reflex arcs, or whether we assume that the reflex function belongs only to the sympathetic, and that the higher functions of the cord and brain are excluded from this reflex. Since every nervous function proceeds upon the principle of a reflex, however, the former supposition seems to be fully justified, and, in matter of fact, Müller admits the importance of the spinal elements of the reflex concerned in a powerful ejaculation. (See above.) In this way the superimposed vesical reflex arcs communicating with the sympathetic would act as supplementary aids in emptying the bladder and rectum. Moreover, there is really no reason to test the qualification of bladder and rectal centers for those reflex centers which control the striated sphincters of these structures (loss of tonus of the sphincter after destruction of the cord—Müller) and, in fact, every voluntary muscle, must possess in the same manner. By the conception of superimposed reflex arcs, however, it seems to the author that the two theories may be made to harmonize. The recorded experiments are not sufficient to decide this question. The preservation of the vesical and rectal functions after destruction of the cord has not as yet been sufficiently explained by experiments, and it must be studied both quantitatively and qualitatively more fully than has been done either clinically or experimentally.

Examining the Vesical and Rectal Functions

In examining the disturbed bladder and rectal functions the following points should be noted:

1. **Fulness** of the bladder and of the rectum—to be determined by palpation and percussion in the case of the bladder, and by digital examination in the case of the rectum.

2. **Condition of the sphincter tonus**—to be determined for the bladder by attempting to expel its contents mechanically or with the help of the catheter; for the rectum, by digital examination.

3. Sensibility of the bladder and rectal mucous membranes.¹ The occurrence or lack of a desire for stool or urination will decide this point. The sensibility of the bladder can also be determined by a catheter; the rectum by a digital examination. Pain or pressure (tenesmus) accompanying evacuation should be heeded.

4. Character of the evacuation: Absolute or partial retention of the urine and feces; overflow of the full bladder and the rectum, with pronounced retention and accentuated sphincter tonus (the real *paradoxic incontinence*). Degree of retention: palpatory determination of the position of the fundus of the bladder; involuntary evacuation by means of the normal reflexes (*enuresis, involuntary defecation*); possibility or impossibility of favoring the reflex involuntary evacuation (incontinence) or of inhibiting it. *Imperative incontinence* is the name applied to a special form of incontinence in which the only way to avoid an involuntary escape of urine or feces is immediately to accede to the very first demand for evacuation. The fact that constipation often occurs without any spinal cord affection makes it difficult to determine practically how much clinical value is to be assigned to the condition of the rectal evacuation. Therefore, before deciding that a constipation depends upon the spinal cord, it is especially important to examine points 1, 2, and 3. In any analysis of the character of evacuation we must also determine whether or not the patient still preserves the sensation of micturition and defecation, being careful to avoid confusing this sensation with that of being wet or soiled.

APPENDIX

The Utility of Routine Plans and Stamped or Printed Figures for Collecting and Tabulating the Results of Examination

ROUTINE PLANS

In tabulating the condition of a patient for certain special purposes it has been found very advantageous at the author's clinic to make use of definite routine plans. In this way nothing important in the examination can be forgotten, and the results will be entered in a careful and summarized fashion. These outlines have proved of so much value, and saved so much time, that it seems worth while to give examples of them.

They are of special value in examining the nervous system, both because the points upon which the complete examination depends are almost too numerous to keep constantly in mind, and because it is especially advantageous in this class of diseases to group the results of examination in an intelligent way. (See p. 946.) Of course, they are also valuable in examining other affections. A few examples will illustrate this, although it scarcely need be mentioned that the outlines may be modified or enlarged at pleasure, according to the special purpose of the examiner. The following examples should in no way be considered as absolute standards, but merely as illustrations of what the author has found useful. Enough space upon the right side of the text should be reserved to enter the necessary notes. For the nervous system it is advisable to leave sufficient space for the data upon both sides, to correspond to the right and left sides of the body. Everything found to be "normal" should be marked so, and everything which has not been examined should be marked "not examined." Naturally, the entire status cannot be settled in every instance by filling out the outlines, because some conditions often require a more detailed description; but the outlines will serve to a certain extent as a nucleus for the entire clinical picture, about which everything else crystallizes. To prevent misunderstanding, the author wishes to call attention to the fact that such outlines do not in any way take the place of the ordinary extended descriptions of the symptoms of disease. Experience shows it to be entirely impractical to use them, except for certain special examinations.

¹ It has not been determined how much actual sensibility the mucous membranes of the bladder and rectum normally possess; nor to what extent the consciousness of a full bladder or rectum is caused by stretching of its nearby soft parts innervated by the spinal nerves. It is possible that, under normal conditions, just as in the case of the intestines, gall-bladder, etc., only the stimuli from the soft parts reach the brain, and that the vesical mucous membrane becomes sensitive only when diseased. (See p. 981.)

Name.

Date.

Appetite.

Stool.

Retention in the morning.

Vomiting (time, character).

Pains (time, character).

CHARACTERISTICS OF THE GASTRIC CONTENTS:¹

The Vomitus: Mucus, blood, leukocytes, meat-fibers, starch, sarcinæ, bacteria.

The Expressed Contents of the Empty Stomach: Mucus, blood, leukocytes, meat-fibers, starch, residue of other food, sarcinæ, bacteria.

The expressed contents of the empty stomach after the withdrawal of the gastric contents on the preceding evening.

BUTYROMETRIC GASTRIC EXAMINATION:

Amount of test-meal prepared . . cc., containing . . gm. flour and . . gm. butter.

Amount of test-meal ingested . . cc.

Expression after . . minutes. Amount expressed (by method of complete evacuation of stomach, p. 444): . . cc.

Acidity of the filtrate of the expressed meal: a . . cc. $\frac{N}{10}$ NaOH to 10 cc. contents = % HCl.

Free HCl $\left\{ \begin{array}{l} = + . . \% \text{ HCl (acid excess).} \\ = - . . \% \text{ HCl (acid deficit).} \end{array} \right.$

Lactic acid: [Shaking with ether].

At percentage of the ingested flour soup (estimated butyrometrically): $F = . . \%$.

At percentage of the expressed flour soup (estimated butyrometrically): $f = . . \%$.

Residual amount of meal: $Su = \frac{f}{F} To = . . \text{ cc. (because } \frac{Su}{To} = \frac{f}{F} \text{).}$

Amount of gastric juice: $Ma = To - Su = . . \text{ cc.}$

Acidity of the pure secretion: $A = \frac{a To}{Ma} = . . \% \text{ (because } \frac{a}{A} = \frac{Ma}{To} \text{).}$

Retention quotient: $\frac{Ma}{Su} =$

Ability quotient: $\frac{\text{the soup which passes through the intestine}}{\text{soup ingested}} =$

Summary of results: $\frac{To}{Su} = \frac{A}{Ma} =$

EXAMINATION OF THE FILTRATE OF THE GASTRIC CONTENTS

Of the Flour Soup Breakfast:

Reaction to free HCl: . . . Phloroglucinvanillin . . . Methyl-violet . . . Tropaeolin . . .

Rennin ferment.

Starch digestion: Coloration of 5 cc. of the gastric juice filtrate after addition of . . cc. of $\frac{N}{100}$ iodid solution.

This color is blue,¹ violet,¹ red.¹

Of digestion with carmin fibrin:

. With unmixed gastric juice.

. With undiluted or acidified gastric juice.

Of the vomitus . . . hours after ingestion of food.

Same with the test-breakfast.

THE DESMOID REACTION

Desmoid capsule taken at noon after soup. The patient ambulant or in bed (lying, sitting) avoiding right lateral posture. (See p. 433.)

Appearance of methylene-blue in urine after . . . hours.

Time after . . . hours.

¹ What is not found should be crossed out.

IODOFORM GLUTOID TEST

Control number of the capsules . .
 Appearance of the first iodid reaction in the saliva after . . hours.
 Duration of the reaction.
 Results on a healthy individual.

4. OUTLINE FOR THE EXAMINATION OF THE NERVOUS SYSTEM

(a) General Outline

Date.

Name.

Sensorium.

Intelligence.

Disposition.

Memory.

Sleep, vertigo.

Speech. (For details, see special scheme, p. 1122.)

Breathing.

Pulse.

Cranial nerves. (For details, see special scheme b, p. 1175.)

Attitude.

Gait (with eyes open and shut).

Standing position (with eyes open and shut).

VOLUNTARY MOTILITY

Neck:

Sternocleidomastoid.

Trapezius.

Other muscles of the neck.

Upper extremity. (For details, see special scheme, p. 1132.)

Gross muscular power.

Coördination.

Lower extremity. (For details, see special scheme, p. 1134.)

Gross muscular power.

Coördination.

Trunk:

Intercostal muscles.

Diaphragm.

Abdominal muscles.

Muscles of the back.

Irritative motor phenomena (clonic, tonic spasms, fibrillary twitchings, tremors, contractures, chorea, athetosis, etc.).

Muscular atrophies:

Electric reaction of the muscles. (For details, see special scheme d, p. 1176.)

SENSIBILITY

(To be represented upon a chart of the body.¹ It should be mentioned here how the sensations of touch, pain, heat, cold, and pressure, etc. were examined.)

¹ See p. 1177.

Head and Neck:

Sensation of touch.
 Bony and cutaneous perception of vibrations.
 Sensation of pain.
 Sensation of heat.
 Sensation of cold.
 Localization of pain and touch.

Upper Extremity:

Sensation of touch.
 Bony and cutaneous perception of vibrations.
 Sensation of pain.
 Sensation of heat.
 Sensation of cold.
 Sensation of pressure.
 Localization of pain and touch.
 Innervation sense, "power sense."
 Appreciation and judgment of the active movements.
 Appreciation of posture.¹
 Appreciation of an object by feeling it (stereognostic sense).

Trunk:

Sensation of touch.
 Bony and cutaneous perception of vibrations.
 Sensation of pain.
 Sensation of heat.
 Sensation of cold.
 Sensation of pressure.
 Localization of pain and touch.

Lower Extremity:

Sensation of touch.
 Bony and cutaneous perception of vibrations.
 Sensation of pain.
 Sensation of heat.
 Sensation of cold.
 Sensation of pressure.
 Localization of pain and touch.
 Innervation sense, "power sense."
 Appreciation and judgment of the active movements.
 Appreciation of posture.²
 Appreciation of an object by feeling it (stereognostic sense).

Spontaneous pains (neuralgias, parenchymatous pains, headache).

Hyperalgesia of the skin.

Sensibility of the nerves and muscles to pressure.

REFLEXES

Cutaneous Reflexes (strength? alteration?).³

Plantar reflex (to pricking).
 Plantar reflex (to tickling).
 Abdominal reflex (upper, lower, middle).
 Cremaster reflex (groin reflex).
 Anal reflex.
 Other reflexes.

Tendon Reflexes.

Patellar reflex.
 Achilles reflex (foot clonus).
 Upper extremity.

Periosteal reflexes.

BLADDER FUNCTIONS

Fulness of the bladder.

Condition of the sphincter tonus (expression of the bladder, finally examining with a catheter.)

Sensibility of the bladder mucous membrane. Desire for evacuation, urgency, tenesmus, pains.

Character of the evacuation: Absolute or partial retention; overflow of a full bladder associated with a marked retention and an increased sphincter tonus (*paradoxical*

¹ See p. 978 et seq.

² See p. 976 et seq.

³ See p. 997, Pathologic Reflexes.

incontinence); degree of retention; overflow of the bladder with a moderate filling and deficient sphincter tonus (*actual paralysis of the bladder*); the position of the fundus (palpation); evacuation through the normal reflex, but involuntarily (*enuresis*); possibility or impossibility of influencing the reflex evacuation, either favoring (incontinence, imperative incontinence, p. 1170) or inhibiting it. Sensation produced by the evacuation to be distinguished from the sensation of the wetting.

FUNCTIONS OF THE RECTUM

Character of the stool evacuation. For the rest, we employ practically the same scheme as for the bladder functions.

Condition of the nervous sexual apparatus. (Potency, etc.)

Trophic disturbances of the skin, hair, nails, decubitus, ulcer perforans, etc.

Vasomotor conditions.

Additional notes.

(b) Outline for the Examination of the Cranial Nerves

Date.

Name.

I. *Olfactory.*

Smell (how tested? cologne water, asafetida, ol. anisi).

Result of rhinoscopic examination.

II. *Optic.*

Central visual acuity (with corrected refraction).

Visual field (hemipia, limitations, fatigue).

Result of ophthalmoscopic examination.

Color blindness (how examined? Holmgren-Pflüger's flower contrast).

III, IV, VI. *Nerves of the Eye Muscles.*

Direction of vision (conjugate deviation).

Conjugate movements.

Unilateral testing of the movements of the eyes.

Double vision.

Convergence (how tested?).

Nystagmus:

Horizontal.

Vertical.

Rotatory.

Pupils:

Size under moderate illumination.

Reaction to light (how tested?).

Direct.

Crossed.

Hemipic rigidity to light (to be tested in hemipia and double blindness, how tested?).

Reaction to accommodation.

Accommodation (how tested?).

V. *Trigeminus.*

Sensory division.

Face.

Forehead.

Conjunctiva and cornea (corneal reflex).

Tongue.

Taste (how tested? salt, acetic acid).

Smell (how tested? acetic acid, ammonia).

Motor division (chewing muscles).

Raising the jaw.

Lateral movement of the jaw.

Atrophy of the chewing muscles.

Electric examination. (See special scheme.)

VII. *Facial.*

Upper branch (forehead, closure of eyes).

Lower branch.

Palate (position, voluntary movement, speech, swallowing, reflex).

Electric examination. (For details, see special scheme.)

Behavior of the facial associated movements.

VII. *Facial (Continued).*

Behavior of the facial emotional movements.
 Corneal reflex, optic facial reflex.
 Mechanical irritability (how tested?).
 Atrophy of the facial muscles.

VIII. *Acoustic.*

Hearing in general.
 Test of the air conduction.
 Test of the bone conduction (von Bezold's modification of Rinne's test).
 Weber's test.
 Schwabach's test.
 Subjective noises, dizziness.
 Results of otoscopic examination.

IX, X, XI. *Glossopharyngeal, Vagus, Accessory.*

Taste (how tested? bitter, sweet?).
 Act of swallowing.
 Voice.
 Breathing and pulse.
 Results of laryngoscopic examination.
 Trapezius, sternocleidomastoideus.
 Atrophies.
 Electric examination. (For details, see special scheme.)

XII. *Hypoglossal.*

Extended movements.
 Position of the tongue when protruded.
 Atrophy of the tongue.
 Fibrillary twitching.
 Electric examination. (For details, see special scheme.)
 Speech. (See special scheme.)

Other Remarks.(c) **Outlines for the Examination of Muscular Atrophies and Peripheral Motor Paralyzes**

For the exact examination of the motility of the individual muscles and the peripheral motor nerves, the Bern Clinic uses the outline found upon pp. 1132-1136. Ample room should be left for the entries, and the outlines for the upper and the lower extremity should be printed upon separate sheets.

(d) **Outlines for Electric Examination**

Corresponding results of examining a
 healthy individual of equal stature
 and constitution, for comparison.

Date.

Name.

Name of the muscle examined.

Size in sq. c. of the stimulation electrode employed.

EXAMINATION OF THE MUSCLE*Faradic Current.*

Rapid interruption. Minimum contraction measured upon the sliding apparatus. Type of contraction.
 Single shocks. Minimum contraction measured upon the sliding apparatus.
 Type of contraction.
 Signs of fatigue.

Galvanic Current.

Minimal CaCC in milliampères. Volt.
 Type of contraction.
 Minimal AnCC in milliampères. Volt.
 Type of contraction.
 Relation of CaCC to AnCC in milliampères. Volt.
 Signs of fatigue.

EXAMINATION OF THE NERVE*Point of Stimulation:**Faradic Current.*

Rapid interruption. Minimal contraction measured upon the sliding apparatus.
 Type of contraction.

Faradic Current (Continued).

Single shocks. Minimal contraction measured upon the sliding apparatus.

Type of contraction.

Signs of fatigue.

Galvanic Current.

Minimal CaCC in milliamperes. Volt.

Type of contraction.

Minimal AnCC in milliamperes. Volt.

Type of contraction.

Relation of CaCC to AnCC in milliamperes. Volt.

Signs of fatigue.

Especial Types of Reactions.

Myotonic reaction, galvanic myokymia, faradic myokymia, neurotonic reaction, myasthenic reaction, alternating contractions during faradic stimulation, myotonomia during faradic stimulation, etc.

(c) Outline for the Examination of the Speech

The summary upon p. 1122 may be utilized as an outline.

CHARTS

Charts are especially useful for recording the results of physical examinations. The fundamental rules recommended for their use are mentioned upon pp. 209 et seq., 217 et seq., 310, 327, 334 to 339, 345, and condensed upon pp. 388 and 408 et seq. They are employed in all the histories in Bern. Upon pp. 223 to 272 and 388 to 421 a large number of examples of pathologic charts are to be found. The charts on pp. 209 to 211—better double the size—are good models. Exact representations are difficult to make upon the ordinary small chart. For routine office practice, however, rubber stamps are very serviceable. In the author's experience the use of pictorial charts, especially, for the designation of pulmonary and cardiac lesions, cannot be too highly recommended. They compel a more thorough examination, in the same way that one who makes sketches during a journey necessarily observes objects more accurately than one who does not. A few strokes of the pencil often mean more to the traveler or diagnostician than a lengthy description.

Charts are quite as essential for representing disturbances of sensibility. The linear reproductions on pp. 1136 to 1141, Figs. 449 to 454, may be used as charts representing circumscribed disturbances of sensibility. Those upon pp. 948 and 985 are better for representing disturbances which affect a large part of the entire body (hemiplegias, paraplegias, hysteric disturbances of sensibility). The variations of sensibility can be best expressed upon these charts by different colors or shading.

Charts are also useful for representing laryngoscopic, rhinoscopic, and otoscopic lesions (Fig. 339, p. 900, and Fig. 357, p. 906).

The results of ophthalmoscopic examination may be very conveniently represented graphically in the sketch-book prepared by Prof. Haab (sold by Hofer Burger, in Zurich). Both plates in this book have been made by means of this sketch-book. The leaves are colored to represent the red ground-tone of the ophthalmoscopic picture. White or yellow shades can be produced by rubbing this ground-color more or less vigorously with an eraser or a knife, and the dark-red and black tones can be added with colored pencils or water-colors. The technic is explicitly described in the sketch-book, and any one can easily acquire facility enough to make very useful pictures.

[NOTE ON THE CAMMIDGE REACTION (p. 596).

Roper and Stillman,¹ after a careful study of the Cammidge reaction, reach the following conclusions: "The 'C reaction,' as proposed by Cammidge, for the demonstration of a characteristic substance in the urine of patients suffering from diseases of the pancreas, does not rest on a firm scientific basis, as all the glycuronic acid is not removed in every instance by the technic of this reaction. The formation of the typical crystals is due to the presence of glycuronic acid. As this substance is present in the urine of persons in normal health, and is increased in amount in many conditions in no way associated with disease of the pancreas, the demonstration of these so-called typical crystals can have no diagnostic value."—Ed.]

SAUNDERS' BOOKS

on

**Pathology, Physiology
Histology, Embryology
and Bacteriology**

W. B. SAUNDERS COMPANY

925 WALNUT STREET

PHILADELPHIA

9, HENRIETTA STREET

COVENT GARDEN, LONDON

LITERARY SUPERIORITY

THE excellent judgment displayed in the publications of the house at the very beginning of its career, and the success of the modern business methods employed by it, at once attracted the attention of leading men in the profession, and many of the most prominent writers of America offered their books for publication. Thus, there were produced in rapid succession a number of works that immediately placed the house in the front rank of Medical Publishers. One need only cite such instances as Keen's five-volume work on Surgery, Kelly and Noble's Gynecology and Abdominal Surgery, Kelly and Cullen's Myomata of the Uterus, Deaderick on Malaria, Bonney's Tuberculosis, Gant's Constipation and Obstruction, Bier's Hyperemic Treatment by Willy Meyer, M. D., and Prof. V. Schmieden, Jordan's Bacteriology, Arny's Pharmacy, and Kemp on Stomach and Intestines. These books have made for themselves a place among the best works on their several subjects.

A Complete Catalogue of our Publications will be Sent upon Request

Jordan's General Bacteriology

A Text-Book of General Bacteriology. By EDWIN O. JORDAN, PH. D., Professor of Bacteriology in the University of Chicago and in Rush Medical College. Octavo of 594 pages, fully illustrated. Cloth, \$3.00 net.

JUST READY—THE NEW (2d) EDITION

FOR MEDICAL AND ACADEMIC STUDENTS

Professor Jordan's new work embraces the entire field of bacteriology, and is the only work in English dealing with all the most prominent phases of the subject. The non-pathogenic as well as the pathogenic bacteria are considered, giving greater emphasis, of course, to the latter. There are extensive chapters on methods of studying bacteria, including staining, biochemical tests, cultures, etc.; on the development and composition of bacteria; on enzymes and fermentation-products; on the bacterial production of pigment, acid and alkali; and on ptomains and toxins. An entire chapter is devoted to each species of bacteria. Especially complete is the presentation of the serum treatment of gonorrhea, diphtheria, dysentery, and tetanus. The relation of bovine to human tuberculosis and the ocular tuberculin reaction receive extensive consideration; and the description of the microörganism of syphilis—the *spirochæta pallida*—presents the latest developments in its study. Especially valuable is the colored illustration of this organism as stained by the method of Levaditi.

This work will also appeal to academic and scientific students. It contains chapters on the bacteriology of plants and of the various arts and industries. Bacteriology of milk and milk-products, of air, agriculture, water, food preservatives, etc., are fully considered. The processes of leather tanning, tobacco curing, and vinegar making are detailed in full, and the bacteriology of these industries carefully presented. There are also chapters on the relation of bacteriology to household administration and to sanitary engineering, and on the bacterial diseases of plants. This latter is a scientific study of those diseases which destroy flowers, fruits, and vegetables.

Prof. Henry Kraemer

Professor of Botany, Pharmacognosy, and Director of the Microscopic Laboratory, Philadelphia College of Pharmacy.

"Professor Jordan's General Bacteriology is a splendid book and we will use it in our course in bacteriology."

Prof. Severance Burrage

Associate Professor of Sanitary Science in Purdue University, Indiana.

"I am much impressed with the completeness and accuracy of the book. It certainly covers the ground more completely than any other American book that I have seen."

Dürck and Hektoen's General Pathologic Histology

Atlas and Epitome of General Pathologic Histology. By PR. DR. H. DÜRCK, of Munich. Edited, with additions, by LUDVIG HEKTOEN, M. D., Professor of Pathology in Rush Medical College, Chicago. 172 colored figures on 77 lithographic plates, 36 text-cuts, many in colors, and 353 pages. Cloth, \$5.00 net. *In Saunders' Hand-Atlas Series.*

This new Atlas will be found even more valuable than the two preceding volumes on Special Pathologic Histology, to which, in a manner, it is a companion work. The text gives the generally accepted views in regard to the significance of pathologic processes, explained in clear and easily understood language. The lithographs in some cases required as many as twenty-six colors to reproduce the original painting. Dr. Hektoen has made many additions of great value.

W. T. Councilman, M. D.,

Professor of Pathologic Anatomy, Harvard University.

"I have seen no plates which impress me as so truly representing histologic appearances as do these. The book is a valuable one."

Howell's Physiology

A Text-Book of Physiology. By WILLIAM H. HOWELL, PH.D., M. D., Professor of Physiology in the Johns Hopkins University, Baltimore, Md. Octavo of 999 pages, 296 illustrations. Cloth, \$4.00 net.

THE NEW (3d) EDITION

Dr. Howell has had many years of experience as a teacher of physiology in several of the leading medical schools, and is therefore exceedingly well fitted to write a text-book on this subject. Main emphasis has been laid upon those facts and views which will be directly helpful in the practical branches of medicine. At the same time, however, sufficient consideration has been given to the experimental side of the science. The entire literature of physiology has been thoroughly digested by Dr. Howell, and the important views and conclusions introduced into his work. Illustrations have been most freely used.

The Lancet, London

"This is one of the best recent text-books on physiology, and we warmly commend it to the attention of students who desire to obtain by reading a general, all-round, yet concise survey of the scope, facts, theories, and speculations that make up its subject matter."

McFarland's Pathology

A Text-Book of Pathology. By JOSEPH MCFARLAND, M. D., Professor of Pathology and Bacteriology in the Medico-Chirurgical College of Philadelphia. Octavo of 856 pages, with 437 illustrations, many in colors. Cloth, \$5.00 net; Half Morocco, \$6.50 net.

THE NEW (2d) EDITION

You cannot successfully treat disease unless you have a practical, *clinical* knowledge of the pathologic changes produced by disease. For this purpose Dr. McFarland's work is well fitted. It was written with just such an end in view—to furnish a ready means of acquiring a thorough training in the subject, a training such as would be of daily help in your practice. For this edition every page has been gone over most carefully, correcting, omitting the obsolete, and adding the new. Some sections have been entirely rewritten. You will find it a book well worth consulting, for it is the work of an authority.

St. Paul Medical Journal

"It is safe to say that there are few who are better qualified to give a résumé of the modern views on this subject than McFarland. The subject-matter is thoroughly up to date."

Boston Medical and Surgical Journal

"It contains a great mass of well-classified facts. One of the best sections is that on the special pathology of the blood."

McFarland's Biology: Medical and General

Biology: Medical and General.—By JOSEPH MCFARLAND, M. D., Professor of Pathology and Bacteriology in the Medico-Chirurgical College of Phila. 12mo, 440 pages, 160 illustrations. Cloth, \$1.75 net.

JUST READY

All of the problems of medical science are in a sense biologic, and many of the problems of biology medical. This work is both a *general* and *medical* biology. The former because it discusses the peculiar nature and reactions of Living Substance generally; the latter because particular emphasis is laid on those subjects of special interest and value in the study and practice of medicine. The problems of blood-relationship, infection, immunity, parasitism, inheritance, mutilation, regeneration, grafting, and senescence have been presented more fully than in other biologic writings. The illustrations will be found of great assistance in understanding the subject.

McFarland's Pathogenic Bacteria

The New (6th) Edition, Revised

A Text-Book Upon the Pathogenic Bacteria. By JOSEPH MCFARLAND, M. D., Professor of Pathology and Bacteriology in the Medico-Chirurgical College of Philadelphia, Pathologist to the Medico-Chirurgical Hospital, Philadelphia, etc. Octavo volume of 709 pages, finely illustrated. Cloth, \$3.50 net.

FULLY ILLUSTRATED

This book gives a concise account of the technical procedures necessary in the study of bacteriology, a brief description of the life-history of the important pathogenic bacteria, and sufficient description of the pathologic lesions accompanying the micro-organismal invasions to give an idea of the origin of symptoms and the causes of death. The illustrations are mainly reproductions of the best the world affords, and are beautifully executed. In this edition the entire work has been practically rewritten, old matter eliminated, and much new matter inserted.

H. B. Anderson, M. D.,

Professor of Pathology and Bacteriology, Trinity Medical College, Toronto.

"The book is a satisfactory one, and I shall take pleasure in recommending it to the students of Trinity College."

The Lancet, London

"It is excellently adapted for the medical students and practitioners for whom it is avowedly written. . . . The descriptions given are accurate and readable."

Hill's Histology and Organography

A Manual of Histology and Organography. By CHARLES HILL, M. D., formerly Assistant Professor of Histology and Embryology, Northwestern University, Chicago. 12mo of 468 pages, 337 illustrations. Flexible leather, \$2.00 net.

THE NEW (2d) EDITION

Dr. Hill's work is characterized by a completeness of discussion rarely met in a book of this size. Particular consideration is given the mouth and teeth.

Pennsylvania Medical Journal

"It is arranged in such a manner as to be easy of access and comprehension. To any contemplating the study of histology and organography we would commend this work."

American Illustrated Dictionary

THE NEW
STANDARD

The New (5th) Edition—Adopted by U. S. Army

The American Illustrated Medical Dictionary. A new and complete dictionary of the terms used in Medicine, Surgery, Dentistry, Pharmacy, Chemistry, and kindred branches; with over 100 new and elaborate tables and many handsome illustrations. By W. A. NEWMAN DORLAND, M. D., Editor of "The American Pocket Medical Dictionary." Large octavo, nearly 880 pages, bound in full flexible leather. Price, \$4.50 net; with thumb index, \$5.00 net.

A KEY TO MEDICAL LITERATURE—WITH 2000 NEW TERMS

Dorland's Dictionary defines hundreds of the newest terms not given in any other dictionary—bar none. These new terms are live, active words, taken right from modern medical literature.

It gives the pronunciation of all words. Many dictionaries give only the accent.

It makes a feature of the derivation or etymology of the words. In some dictionaries the etymology occupies only a secondary place, in many cases no derivation being given at all. In "Dorland," practically every word is given its derivation.

In "Dorland" every word has a separate paragraph, thus making it easy to find a word quickly.

The tables of arteries, muscles, nerves, veins etc., are of the greatest help in assembling anatomic facts. In them are classified for quick study all the necessary information about the various structures.

In "Dorland" every word is given its definition—a definition that *defines* in the fewest possible words. In some dictionaries hundreds of words are not defined at all, referring the reader to some other source for the information he wants at once.

Howard A. Kelly, M. D., *Johns Hopkins University, Baltimore*

"Dr. Dorland's dictionary is admirable. It is so well gotten up and of such convenient size. No errors have been found in my use of it."

J. Collins Warren, M. D., LL.D., F.R.C.S. (Hon.), *Harvard Medical School*

"I regard it as a valuable aid to my medical literary work. It is very complete and of convenient size to handle comfortably. I use it in preference to any other."

Stengel's Text-Book of Pathology

The New (5th) Edition

A Text-Book of Pathology. By ALFRED STENGEL, M. D., Professor of Clinical Medicine in the University of Pennsylvania. Octavo volume of 979 pages, with 400 text-illustrations, many in colors, and 7 full-page colored plates. Cloth, \$5.00 net; Sheep or Half Morocco, \$6.50 net.

WITH 400 TEXT-CUTS, MANY IN COLORS, AND 7 COLORED PLATES

In this work the practical application of pathologic facts to clinical medicine is considered more fully than is customary in works on pathology. While the subject of pathology is treated in the broadest way consistent with the size of the book, an effort has been made to present the subject from the point of view of the clinician. In the second part of the work the pathology of individual organs and tissues is treated systematically and quite fully under subheadings that clearly indicate the subject-matter to be found on each page. In this edition the section dealing with General Pathology has been most extensively revised, several of the important chapters having been practically rewritten. A very useful addition is an Appendix treating of the technic of pathologic methods, giving briefly the most important methods at present in use for the study of pathology, including, however, only those methods capable of giving satisfactory results. The book will be found to maintain fully its popularity.

PERSONAL AND PRESS OPINIONS

William H. Welch, M. D.,

Professor of Pathology, Johns Hopkins University, Baltimore, Md.

"I consider the work abreast of modern pathology, and useful to both students and practitioners. It presents in a concise and well-considered form the essential facts of general and special pathologic anatomy, with more than usual emphasis upon pathologic physiology."

Ludvig Hektoen, M. D.,

Professor of Pathology, Rush Medical College, Chicago.

"I regard it as the most serviceable text-book for students on this subject yet written by an American author."

The Lancet, London

"This volume is intended to present the subject of pathology in as practical a form as possible, and more especially from the point of view of the 'clinical pathologist.' These subjects have been faithfully carried out, and a valuable text-book is the result. We can most favorably recommend it to our readers as a thoroughly practical work on clinical pathology."

Mallory and Wright's Pathologic Technique

Fourth Edition, Revised and Enlarged

Pathologic Technique. A Practical Manual for Workers in Pathologic Histology, including Directions for the Performance of Autopsies and for Clinical Diagnosis by Laboratory Methods. By FRANK B. MALLORY, M. D., Associate Professor of Pathology, Harvard University; and JAMES H. WRIGHT, M. D., Director of the Pathologic Laboratory, Massachusetts General Hospital. Octavo of 480 pages, with 152 illustrations. Cloth, \$3.00 net.

WITH CHAPTERS ON POST-MORTEM TECHNIQUE AND AUTOPSIES

In revising the book for the new edition the authors have kept in view the needs of the laboratory worker, whether student, practitioner, or pathologist, for a practical manual of histologic and bacteriologic methods in the study of pathologic material. Many parts have been rewritten, many new methods have been added, and the number of illustrations has been considerably increased. Among the new matter may be mentioned, as of particular interest, Zinsser's anaerobic method for plate cultures; the ox-bile method, the medium of Endo, and the malachite-green medium for typhoid bacillus; Wright's method for blood-platelets and bone-marrow giant cells; Best's improved stain for glycogen; von Kossa's silver method for lime-salts; Levaditi's method of staining the spirochæta pallida; and Sir A. E. Wright's bacterial vaccines. The paragraphs on the micro-organism of actinomycosis have been rewritten. The work continues to be a most useful laboratory and post-mortem guide, full of practical information.

PERSONAL AND PRESS OPINIONS

Wm. H. Welch, M. D.,

Professor of Pathology, Johns Hopkins University, Baltimore.

"I have been looking forward to the publication of this book, and I am glad to say that I find it a most useful laboratory and post-mortem guide, full of practical information and well up to date."

Boston Medical and Surgical Journal

"This manual, since its first appearance, has been recognized as the standard guide in pathological technique, and has become well-nigh indispensable to the laboratory worker."

Journal of the American Medical Association

"One of the most complete works on the subject, and one which should be in the library of every physician who hopes to keep pace with the great advances made in pathology."

Heisler's Text-Book of Embryology

The New (3d) Edition

A Text-Book of Embryology. By JOHN C. HEISLER, M.D., Professor of Anatomy in the Medico-Chirurgical College, Philadelphia. Octavo volume of 435 pages, with 212 illustrations, 32 of them in colors. Cloth, \$3.00 net.

WITH 212 ILLUSTRATIONS, 32 IN COLORS

The fact of embryology having acquired in recent years such great interest in connection with the teaching and with the proper comprehension of human anatomy, it is of first importance to the student of medicine that a concise and yet sufficiently full text-book upon the subject be available. This new edition represents all the latest advances recently made in the science of embryology. Many portions have been entirely rewritten, and a great deal of new and important matter added. A number of new illustrations have also been introduced and these will prove very valuable. The previous editions of this work filled a gap most admirably, and this new edition will undoubtedly maintain the reputation already won. Heisler's Embryology has become a standard work.

PERSONAL AND PRESS OPINIONS

G. Carl Huber, M. D.,

Professor of Histology and Embryology, University of Michigan, Ann Arbor.

"I find the second edition of 'A Text-Book of Embryology' by Dr. Heisler an improvement on the first. The figures added increase greatly the value of the work. I am again recommending it to our students."

William Wathen, M. D.,

Professor of Obstetrics, Abdominal Surgery, and Gynecology, and Dean, Kentucky School of Medicine, Louisville, Ky.

"It is systematic, scientific, full of simplicity, and just such a work as a medical student will be able to comprehend."

Birmingham Medical Review, England

"We can most confidently recommend Dr. Heisler's book to the student of biology or medicine for his careful study, if his aim be to acquire a sound and practical acquaintance with the subject of embryology."

Wells' Chemical Pathology

Chemical Pathology.—Being a Discussion of General Pathology from the Standpoint of the Chemical Processes Involved. By H. GIDEON WELLS, PH. D., M. D., Assistant Professor of Pathology in the University of Chicago. Octavo of 549 pages. Cloth, \$3.25 net.

A PRACTICAL BOOK

Dr. Wells' work is written for the physician, for those engaged in research in pathology and physiologic chemistry, and for the medical student. In the introductory chapter are discussed the chemistry and physics of the animal cell, giving the essential facts of ionization, diffusion, osmotic pressure, etc., and the relation of these facts to cellular activities. Special chapters are devoted to *Diabetes* and to *Uric-acid Metabolism and Gout*.

Wm. H. Welch, M. D.

Professor of Pathology, Johns Hopkins University.

"The work fills a real need in the English literature of a very important subject, and I shall be glad to recommend it to my students."

Lusk's Elements of Nutrition

Elements of the Science of Nutrition. By GRAHAM LUSK, PH. D., Professor of Physiology at Cornell Medical School. Octavo volume of 302 pages. Cloth, \$3.00 net.

THE NEW (2d) EDITION

Prof. Lusk presents the scientific foundations upon which rests our knowledge of nutrition and metabolism, both in health and in disease. There are special chapters on the metabolism of diabetes and fever, and on purin metabolism. The work will also prove valuable to students of *animal dietetics* at agricultural stations.

Lewellys F. Barker, M. D.

Professor of the Principles and Practice of Medicine, Johns Hopkins University.

"I shall recommend it highly to my students. It is a comfort to have such a discussion of the subject in English."

Böhm, Davidoff, and Huber's Histology

A Text-Book of Human Histology. Including Microscopic Technic. By DR. A. A. BÖHM and DR. M. VON DAVIDOFF, of Munich, and G. GARL HUBER, M. D., Professor of Histology and Embryology in the University of Michigan, Ann Arbor. Handsome octavo of 528 pages, with 361 beautiful original illustrations. Flexible cloth, \$3.50 net.

THE NEW (2d) EDITION, ENLARGED

The work of Drs. Böhm and Davidoff is well known in the German edition, and has been considered one of the most practically useful books on the subject of Human Histology. This second edition has been in great part rewritten and very much enlarged by Dr. Huber, who has also added over one hundred original illustrations. Dr. Huber's extensive additions have rendered the work the most complete students' text-book on Histology in existence.

Boston Medical and Surgical Journal

"Is unquestionably a text-book of the first rank, having been carefully written by thorough masters of the subject, and in certain directions it is much superior to any other histological manual."

Drew's Invertebrate Zoölogy

A Laboratory Manual of Invertebrate Zoölogy. By GILMAN A. DREW, PH.D., Professor of Biology at the University of Maine. With the aid of Members of the Zoölogical Staff of Instructors of the Marine Biological Laboratory, Woods Holl, Mass. 12mo of 200 pages. Cloth, \$1.25 net.

A LABORATORY WORK

The subject is presented in a logical way, and the type method of study has been followed, as this method has been the prevailing one for many years.

Prof. Allison A. Smyth, Jr., Virginia Polytechnic Institute

"I think it is the best laboratory manual of zoölogy I have yet seen. The large number of forms dealt with makes the work applicable to almost any locality."

American Text-Book of Pathology

American Text-Book of Pathology. Edited by LUDVIG HEKTOEN, M. D., Professor of Pathology, Rush Medical College, in affiliation with the University of Chicago; and DAVID RIESMAN, M. D., Professor of Clinical Medicine, Philadelphia Polyclinic. Handsome imperial octavo, 1245 pages, 443 illustrations, 66 in colors. Cloth, \$7.50 net; Sheep or Half Morocco, \$9.00 net.

MOST SUMPTUOUSLY ILLUSTRATED PATHOLOGY IN ENGLISH

The present work is the most representative treatise on the subject that has appeared in English. It furnishes practitioners and students with a comprehensive text-book on the essential principles and facts in General Pathology and Pathologic Anatomy, with especial emphasis on the relations of the latter to practical medicine. The illustrations are nearly all original, and those in color are printed directly in the text. In fact, the pictorial feature of the work forms a complete atlas of pathologic anatomy and histology.

Quarterly Medical Journal, Sheffield, England

"As to the illustrations, we can only say that whilst all of them are good, most of them are really beautiful, and for them alone the book is worth having. Both colored and plain, they are distributed so profusely as to add very largely to the interest of the reader and to help the student."

McConnell's Pathology

A Manual of Pathology. By GUTHRIE MCCONNELL, M. D., Pathologist to the Skin and Cancer Hospital, St. Louis. 12mo of 523 pages, with 170 illustrations. Flexible leather, \$2.50 net.

Dr. McConnell has discussed his subject with a clearness and precision of style that render the work of great assistance to both student and practitioner. The illustrations have been introduced for their practical value.

New York State Journal of Medicine

"The book treats the subject of pathology with a thoroughness lacking in many works of greater pretension. The illustrations—many of them original—are profuse and of exceptional excellence."

Dürck and Hektoen's Special Pathologic Histology

Atlas and Epitome of Special Pathologic Histology. By DR. H. DÜRCK, of Munich. Edited, with additions, by LUDVIG HEKTOEN, M. D., Professor of Pathology, Rush Medical College, Chicago. In two parts. Part I.—Circulatory, Respiratory, and Gastro-intestinal Tracts. 120 colored figures on 62 plates, and 158 pages of text. Part II.—Liver, Urinary and Sexual Organs, Nervous System, Skin, Muscles, and Bones. 123 colored figures on 60 plates, and 192 pages of text. Per part: Cloth, \$3.00 net. *In Saunders' Hand-Atlas Series.*

The great value of these plates is that they represent in the exact colors the effect of the stains, which is of such great importance for the differentiation of tissue. The text portion of the book is admirable, and, while brief, it is entirely satisfactory in that the leading facts are stated, and so stated that the reader feels he has grasped the subject extensively.

William H. Welch, M. D.,

Professor of Pathology, Johns Hopkins University, Baltimore.

"I consider Dürck's 'Atlas of Special Pathologic Histology,' edited by Hektoen, a very useful book for students and others. The plates are admirable."

Sobotta and Huber's Human Histology

Atlas and Epitome of Human Histology. By PRIVATDOCENT DR. J. SOBOTTA, of Würzburg. Edited, with additions, by G. CARL HUBER, M. D., Professor of Histology and Embryology in the University of Michigan, Ann Arbor. With 214 colored figures on 80 plates, 68 text-illustrations, and 248 pages of text. Cloth, \$4.50 net. *In Saunders' Hand-Atlas Series.*

INCLUDING MICROSCOPIC ANATOMY

The work combines an abundance of well-chosen and most accurate illustrations, with a concise text, and in such a manner as to make it both atlas and text-book. The great majority of the illustrations were made from sections prepared from human tissues, and always from fresh and in every respect normal specimens. The colored lithographic plates have been produced with the aid of over thirty colors.

Boston Medical and Surgical Journal

"In color and proportion they are characterized by gratifying accuracy and lithographic beauty."

Levy and Klemperer's Clinical Bacteriology

The Elements of Clinical Bacteriology. By DRS. ERNST LEVY and FELIX KLEMPERER, of the University of Strasburg. Translated and edited by AUGUSTUS A. ESHNER, M. D., Professor of Clinical Medicine, Philadelphia Polyclinic. Octavo volume of 440 pages, fully illustrated. Cloth, \$2.50 net.

S. Solis-Cohen, M. D.,

Professor of Clinical Medicine, Jefferson Medical College, Philadelphia.

"I consider it an excellent book. I have recommended it in speaking to my students."

Lehmann, Neumann, and Weaver's Bacteriology

Atlas and Epitome of Bacteriology: INCLUDING A TEXT-BOOK OF SPECIAL BACTERIOLOGIC DIAGNOSIS. By PROF. DR. K. B. LEHMANN and DR. R. O. NEUMANN, of Würzburg. *From the Second Revised and Enlarged German Edition.* Edited, with additions, by G. H. WEAVER, M. D., Assistant Professor of Pathology and Bacteriology, Rush Medical College, Chicago. In two parts. Part I.—632 colored figures on 69 lithographic plates. Part II.—511 pages of text, illustrated. Per part: Cloth, \$2.50 net. *In Saunders' Hand-Atlas Series.*

Lewis' Anatomy and Physiology for Nurses

Anatomy and Physiology for Nurses. By LEROY LEWIS, M. D., Surgeon to and Lecturer on Anatomy and Physiology for Nurses at the Lewis Hospital, Bay City, Michigan. 12mo of 375 pages, with 150 illustrations. Cloth, \$1.75 net.

THE NEW (2d) EDITION

Nurses Journal of the Pacific Coast

"It is not in any sense rudimentary, but comprehensive in its treatment of the subjects in hand."

Eyre's Bacteriologic Technique

THE ELEMENTS OF BACTERIOLOGIC TECHNIQUE. A Laboratory Guide for the Medical, Dental, and Technical Student. By J. W. H. EYRE, M. D., F. R. S. Edin., Lecturer on Bacteriology at the Medical and Dental Schools, London. Octavo of 375 pages, with 170 illustrations. Cloth, \$2.50 net.

American Text-Book of Physiology **Second Edition**

AMERICAN TEXT-BOOK OF PHYSIOLOGY. In two volumes. Edited by WILLIAM H. HOWELL, PH. D., M.D., Professor of Physiology in the Johns Hopkins University, Baltimore, Md. Two royal octavos of about 600 pages each, illustrated. Per volume: Cloth, \$3.00 net; Half Morocco, \$4.25 net.

"The work will stand as a work of reference on physiology. To him who desires to know the status of modern physiology, who expects to obtain suggestions as to further physiologic inquiry, we know of none in English which so eminently meets such a demand."—*The Medical News*.

Warren's Pathology and Therapeutics **Second Edition**

SURGICAL PATHOLOGY AND THERAPEUTICS. By JOHN COLLINS WARREN, M. D., LL.D., F. R. C. S. (Hon.), Professor of Surgery, Harvard Medical School. Octavo, 873 pages, 136 relief and lithographic illustrations, 33 in colors. With an Appendix on Scientific Aids to Surgical Diagnosis and a series of articles on Regional Bacteriology. Cloth, \$5.00 net; Half Morocco, \$6.50 net.

Gorham's Bacteriology

A LABORATORY COURSE IN BACTERIOLOGY. For the Use of Medical, Agricultural, and Industrial Students. By FREDERIC P. GORHAM, A. M., Associate Professor of Biology in Brown University, Providence, R. I., etc. 12mo of 192 pages, with 97 illustrations. Cloth, \$1.25 net.

"One of the best students' laboratory guides to the study of bacteriology on the market. . . . The technic is thoroughly modern and amply sufficient for all practical purposes."—*American Journal of the Medical Sciences*.

Raymond's Physiology **New (3d) Edition**

HUMAN PHYSIOLOGY. By JOSEPH H. RAYMOND, A. M., M. D., Professor of Physiology and Hygiene, Long Island College Hospital, New York. Octavo of 685 pages, with 444 illustrations. Cloth, \$3.50 net.

"The book is well gotten up and well printed, and may be regarded as a trustworthy guide for the student and a useful work of reference for the general practitioner. The illustrations are numerous and are well executed."—*The Lancet*, London.

Ball's Bacteriology**Sixth Edition, Revised**

ESSENTIALS OF BACTERIOLOGY: being a concise and systematic introduction to the Study of Micro-organisms. By M. V. BALL, M. D., Late Bacteriologist to St. Agnes' Hospital, Philadelphia. 12mo of 289 pages, with 135 illustrations, some in colors. Cloth, \$1.00 net. *In Saunders' Question-Compend Series.*

"The technic with regard to media, staining, mounting, and the like is culled from the latest authoritative works."—*The Medical Times*, New York.

Budgett's Physiology**New (3d) Edition**

ESSENTIALS OF PHYSIOLOGY. Prepared especially for Students of Medicine, and arranged with questions following each chapter. By SIDNEY P. BUDGETT, M. D., formerly Professor of Physiology, Washington University, St. Louis. Revised by HAVAN EMERSON, M. D., Demonstrator of Physiology, Columbia University. 12mo volume of 250 pages, illustrated. Cloth, \$1.00 net. *Saunders' Question-Compend Series.*

"He has an excellent conception of his subject. . . It is one of the most satisfactory books of this class"—*University of Pennsylvania Medical Bulletin.*

Leroy's Histology**New (4th) Edition**

ESSENTIALS OF HISTOLOGY. By LOUIS LEROY, M. D., Professor of Histology and Pathology, Vanderbilt University, Nashville, Tennessee. 12mo, 263 pages, with 92 original illustrations. Cloth, \$1.00 net. *In Saunders' Question-Compend Series.*

"The work in its present form stands as a model of what a student's aid should be; and we unhesitatingly say that the practitioner as well would find a glance through the book of lasting benefit."—*The Medical World*, Philadelphia.

Barton and Wells' Medical Thesaurus

A THESAURUS OF MEDICAL WORDS AND PHRASES. By WILFRED M. BARTON, M. D., Assistant Professor of Materia Medica and Therapeutics, and WALTER A. WELLS, M. D., Demonstrator of Laryngology, Georgetown University, Washington, D. C. 12mo, 534 pages. Flexible leather, \$2.50 net; thumb indexed, \$3.00 net.

American Pocket Dictionary**Sixth Edition**

DORLAND'S POCKET MEDICAL DICTIONARY. Edited by W. A. NEWMAN DORLAND, M. D., Assistant Obstetrician to the Hospital of the University of Pennsylvania. Containing the pronunciation and definition of the principal words used in medicine and kindred sciences, with 64 extensive tables. Containing 598 pages. Flexible leather, with gold edges, \$1.00 net; with patent thumb index, \$1.25 net.

"I can recommend it to our students without reserve."—J. H. HOLLAND, M. D., of the *Jefferson Medical College*, Philadelphia.
